PRESENTED BY

Dr. Stewart Roberts

RECOMMENDATION.

MESSRS. HARPER & BROTHERS,
GENTLEMEN,

It is deemed unnecessary in this note to advance one word in behalf of the great work of Professor Samuel Cooper, of London. The labours of that author have been so long before the public, have received so extensive a patronage by the cultivators of medical and surgical knowledge throughout Europe and in this country, as to place the Surgical Dictionary in the very first rank of those undertakings which have enabled the science of which it treats, and rendered it indispensable to every student and practitioner of the healing art. Our business on the present occasion is to renew to you our thanks for the most acceptable edition with which you have just favoured the profession, of that vast repository of surgical literature and science. In the present reprint we find you have carefully embodied the great mass of original matter which the author has inserted in his seventh and last edition, and have also again commanded the talents of the same able and efficient editor, Professor Reese, to enrich the work still farther with a becoming record of the great achievements in the operative departments of chirurgical art which American skill and intrepidity have made known.

We are free to assert that the labours of Professor Reese have been executed with great fidelity, and may justly be looked upon as the result of a diligent investigation into the merits and services of American surgeons throughout the Union, drawn up with commendable zeal and impartiality. Critical as the task may have been, Professor Reese has evinced peculiar dexterity in its execution, and has excited in the minds of his fellow-labourers in the cause of humanity admiration of the talents he has displayed, and gratitude for the accession of knowledge which he has so advantageously placed within their reach. The Old World will have additional reasons in this excellent digest

RECOMMENDATIONS.

of American Surgery by Dr. Reese, to estimate in a still more favourable light this branch of professional science as cultivated by the New.

VALENTINE MOTT, M.D.,

Professor of Surgery in the University of New-York.

ALEX. H. STEVENS, M.D.,

Emeritus Professor of Clinical Surgery in the College of Physicians and Surgeons, New-York.

JOHN W. FRANCIS, M.D.,

Formerly Professor in the College of Physicians and Surgeons, N. Y.

WILLARD PARKER, M.D.,

Professor of Surgery in the College of Physicians and Surgeons, N. Y.

WILLIAM DETMOLD, M.D., N. Y.

GEO. McCLELLAN, M.D.,

Professor of Surgery in the Pennsylvania Medical College, Philadelphia.

T. D. MUTTER, M.D.,

Professor of Surgery in Jefferson Medical College, Philadelphia.

NATHAN R. SMITH, M.D.,

Professor of Surgery in the University of Maryland, Baltimore.

H. WILLIS BAXLEY, M.D.,

Professor of Anatomy and Surgery in the Washington University of Baltimore.

J. W. R. DUNBAR, M.D.,

Late Professor of Surgery in the Washington University of Baltimore.

A similar testimonial of the merits of this new American edition has also been received, bearing the signature of

WM. GIBSON, M.D.,

Professor of Surgery in the University of Pennsylvania.

Professor Cooper, of London, writes to the American editor, under date of October 24, 1842, as follows:

"I take the earliest opportunity of expressing to you the pleasure I experience in hearing of the advanced state of another American edition of my Dictionary. I think myself fortunate in having a gentleman of your professional attainments to bring my work out in America, enriched with numerous valuable observations collected in the field of experience there. The new edition, I have no doubt, will evince the same candour and love of truth, the same ability, and the same desire to promote the cultivation of scientific and practical surgery, so convincingly manifested in all that you did for the improvement of the former edition. Your testimonials of the merits of your distinguished countrymen will not be overlooked in future editions of my work, &c.

SAMUEL COOPER."

A
DICTIONARY
OF
PRACTICAL SURGERY:

COMPREHENDING

ALL THE MOST INTERESTING IMPROVEMENTS, FROM THE EARLIEST
TIMES DOWN TO THE PRESENT PERIOD;

AN ACCOUNT OF THE INSTRUMENTS AND REMEDIES EMPLOYED IN
SURGERY;

THE ETYMOLOGY AND SIGNIFICATION
OF THE
PRINCIPAL TERMS;

AND NUMEROUS REFERENCES TO ANCIENT AND MODERN WORKS,
FORMING A CATALOGUE OF SURGICAL LITERATURE, ARRANGED ACCORDING
TO SUBJECTS.

BY SAMUEL COOPER,

SENIOR SURGEON TO THE UNIVERSITY COLLEGE HOSPITAL; PROFESSOR OF SURGERY IN THE SAME COL-
LEGE; SURGEON TO THE QUEEN'S BENCH, &c., &c., &c.

FROM THE SEVENTH LONDON EDITION,

REVISED, CORRECTED, AND ENLARGED.

WITH NUMEROUS NOTES AND ADDITIONS, EMBRACING ALL THE PRIN-
CIPAL IMPROVEMENTS AND GREATER OPERATIONS INTRO-
DUCED AND PERFORMED BY AMERICAN SURGEONS.

TOGETHER WITH A

SUPPLEMENTARY INDEX,

IN WHICH THE SCIENCE OF SURGERY IS BROUGHT DOWN TO THE PRE-
SENT PERIOD, INCLUDING ALL THE RECENT IMPROVE-
MENTS IN EUROPE AND AMERICA.

BY DAVID MEREDITH REESE, A.M., M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF PHYSIC, AND OF THE PRINCIPLES OF SURGERY IN CAN-
TLETON MEDICAL COLLEGE, VERMONT; AND PROFESSOR OF THE INSTITUTE OF MEDICINE AND
SURGERY AND MEDICAL JURISPRUDENCE IN THE WASHINGTON UNIVERSITY OF BALTI-
MORE; HONORARY MEMBER OF THE MEDICAL AND CHIRURGICAL FACULTY OF
MARYLAND; MEMBER OF THE MEDICAL SOCIETIES OF MARYLAND
AND PENNSYLVANIA, &c., &c.

PREFACE

BY THE AMERICAN EDITOR.

THE exalted reputation acquired by this Dictionary having obtained for it almost exclusive preference in Great Britain, on the Continent, and throughout the United States, it will be altogether unnecessary for the publishers to introduce the work or its distinguished author to the American public by any new testimonials. Nor will it be expected of the American editor to attempt a laboured commendation of this compendium of surgical literature, with the view of attracting a larger share of attention from the profession than it has already received in its former publications in this country. It has long been esteemed a standard work, is adopted as a text-book in our universities, colleges, and schools of medicine generally, and finds a place in the library of every surgeon in the country.

The first republication in this country was edited by the late distinguished Dr. Dorsey, of Philadelphia; whose valuable improvements carried it through a second and third edition; and under the title of "Dorsey's Cooper," it rapidly gained upon public favour. The author availed himself of most of the American additions in revising his work for a fourth edition, from which it was again reprinted in America, with an appendix, by Mr. Wm. Anderson, of New-York.

Since that time, Mr. Cooper has published a fifth, and recently a sixth edition, improving and enlarging the work by availing himself of the new and valuable discoveries in surgical knowledge to which he has access; and from this last revision of 1830, the present stereotype edition is republished. And as it has passed through two revisions by the author since it was printed in America, and the last includes all that is novel and interesting among British and continental surgeons down to the present year; its republication, even without any semblance of improvement, will be acknowledged to be a desideratum by all who would keep pace with their improving profession.

As in every species of human science our highest attainments are but an approximation towards perfection, so in the science of surgery, each succeeding year demonstrates that all that is known of the principles or practice of our art, is but the prelude to still higher exhibitions of science and skill, alike honourable to the profession, and valuable to the cause of humanity. To condense and arrange all the novel and interesting facts which clinical experience is furnishing, and upon which alone the edifice of true science can be erected, is a task worthy of the immense labour which Mr. Cooper has bestowed on each succeeding reprint of his Dictionary, and one to which he has proved himself entirely adequate. The extensive and multiplied resources to which he has access, furnish him with facilities possessed by few; and in availing himself of these, he has exhibited an industry, and, for the most part, an impartiality, worthy of all praise.

Within the last few years, our profession, and especially the department of Surgery, has been making steady, and even rapid advances in almost every country. Many diseases formerly among the opprobria of our profession have yielded to the science and skill of modern surgeons. Besides the vast improvements made in the treatment of surgical diseases, operations have been performed with entire success for the relief of injuries, but a few years ago esteemed irremediable; and some of them of so bold and difficult a character, that to propose them would have been a hazard of reputation which but few could have then survived.

Learning is not indigenous to any country; and although national pride sometimes prompts to exclusive pretensions, yet the history of surgery, so far as this is concerned, forbids such presumptuous arrogance. The question, "Who hears of American surgeons?" is no longer tauntingly repeated; since the discoveries and operations of some of them have extorted a tribute of admiration from almost every country where this science is cultivated, and given to their names professional immortality. In this, as in the other departments of learning, we may be allowed to say, without the imputation of vanity, that our countrymen have shown to demonstration, that when the tree of science is transplanted across the Atlantic, it is capable of taking as firm a root as in its native soil.

The improvements which surgery has received in the United States, and especially within a few years, although highly important to the interests of the profession and to the cause of suffering humanity, are far from being generally known even in our own country, and still less to the profession abroad. Our periodicals containing them have but a limited circulation, and local views have multiplied their number, until many of the States, and most of our medical institutions, have a vehicle of their own; thus still farther contracting the sphere of their usefulness. And although several of them are most ably conducted, and are adapted to general circulation, we are yet without the advantages which would result from a periodical, strictly national, in which the whole profession might combine their energies for the promotion of science, and to which all might have free and equal access.

From these periodicals our European brethren obtain their information relative to the state and progress of medical and surgical science among us, and some of them never find their way either into Great Britain, France, or Germany. Hence foreign authors are so often charged with criminal remissness in their notices of American surgery. But when we advert to the small proportion of the surgical improvements of this country which have ever been published at all, and recollect that of these but a few are ever seen by our British or continental brethren, we may find an apology for much of the neglect of which we have complained.

That there has been a disposition on the part of some European writers to pass over in silence every thing American, has long been a subject of remonstrance; and in relation to some of these, there is doubtless just ground of complaint. How far Mr. Cooper will be found in the same condemnation will be estimated by those who peruse the present edition, and who will, of course, award him due praise for so much as he has said of American surgery. It is difficult to believe that he has introduced all he knew on this subject, and it is certain that he might have known much more equally worthy of his notice.

In preparing the present edition for the press, the publishers have desired that it might include all that is novel and interesting among American surgeons; and

have committed to the present editor the task of collecting and arranging the materials furnished by our periodicals and original publications, and of condensing these with such original matter as he might be able to obtain, sufficiently important to merit introduction into this Dictionary.

To perform this duty in a manner which should be acceptable to the profession and useful to the community, no pains or labour has been spared. How far he has succeeded in this humble task of compiling from the productions of his fellow-countrymen an epitome of American surgery, remains to be adjudged by those for whose benefit he has been thus employed. He claims no merit for himself, other than that of having rendered, as far as possible, equal and exact justice to the claims of gentlemen in every part of our common country, whether living or dead; and for this purpose, he has availed himself of every accessible means.

He has corresponded with distinguished surgeons in various and remote parts of the land, from many of whom he has received communications of great merit and practical importance. To the periodicals of the last few years he has had frequent recourse, and from most of them he has extracted improvements and inventions which cannot fail to interest and instruct. He must also acknowledge his obligations to Dr. Gross's edition of *Tavernier's Operative Surgery*; Dr. Sterling's translation of *Valpean's Surgical Anatomy*; and to the late Philadelphia edition of *Cooper's First Lines*, with notes by Professor Stevens, of New-York, and the "Philadelphia Editor."

To a number of his professional friends in New-York, as well as in distant parts of the United States, the editor is greatly indebted, not only for the assistance rendered, but for the encouragement they have given him in the performance of this duty. And although he has not heard from some who had promised communications, yet he has availed himself of their published works, and introduced all the operations they claim, so far as his limits would permit.

The limits assigned him by the publishers for enlarging the work, have rendered it necessary to abbreviate and condense many new and important surgical improvements more than was agreeable to his own wishes; and this must be his apology for so frequent reference to the works and periodicals in which they are recorded at length. The same reason will account for the brevity of many of the notes, which consist of mere hints, upon which some amplification would have been more congenial to his own views, and perhaps more acceptable to the profession. It is but an act of justice, however, on the part of the editor towards the publishers to state, that they have suffered him to transcend their limits very considerably, and allowed him a brief appendix for the purpose of introducing some articles unavoidably omitted under their appropriate heads.

It will be perceived by those who have the opportunity of comparing this with the late London edition, as revised and enlarged by the author, that it contains the whole of the matter of that edition, although the size of the type has somewhat diminished the number of pages. Although many of the terms, doctrines, and operations are now obsolete, and might very plausibly be omitted, yet as Mr. Cooper has seen fit to retain them, it has been thought best to make no alteration whatever in the work, and hence also the long catalogue of references at the end of each article is preserved, although many of the works cannot be obtained in this country.

The original matter introduced by the American editor will be found im-

bodied in the text, in immediate connexion with the subject to which it refers, except where an occasional foot note for obvious reasons has been preferred. To distinguish it from the rest, it is included within brackets, and at the close of each of these additions will be found the surname of the editor.

This method of making interpolations in the body of the work may appear less imposing than an array of additions in an appendix at the end of the book, or a display of notes at the foot of the pages, distinguished by asterisks, obelisks, &c.; but they will certainly be found more convenient to the student, and more in conformity to the character of a dictionary. It is from this conviction that this course has been pursued; which, it is hoped, will be satisfactory to the profession.

As the work is stereotyped, it will be necessary in future editions to enlarge the appendix, which can be done to any desirable extent, and the Dictionary may thus keep pace with the steady advancement of surgical knowledge in this and other countries. For the purpose of supplying any omissions which may have been inadvertently made, it is intended at first to publish but a small edition, sufficient to supply the present demand, and any communications from American surgeons will receive respectful notice in a future edition, by being included in the appendix at the close of the second volume. Such communications are respectfully solicited, and may be forwarded to the editor without delay.

To rescue American surgery from unmerited neglect, and to present to our transatlantic brethren a brief epitome of what is doing in the United States for the promotion and improvement of surgical science, is the object at which the editor has directed this effort. That his task has been imperfectly performed he is fully conscious, nor will he affect to conceal his own misgivings in thus attempting to improve upon the work of one of the master-spirits of the other hemisphere. How far the haste with which the work has been hurried through the press, to supply the great demand which is every where felt and expressed, may have contributed to his imperfections, he will not attempt to determine; perhaps his inexperience in such a vocation may be more plausibly urged. His design, however, is now completed; and he submits the result to his brethren in the profession, and to students of this noble science, with no other wish than that it may contribute to elevate our national character, and excite to the still further cultivation and improvement of surgical literature.

DAVID MEREDITH REESE, M.D.

New-York, August 22d, 1830.

PREFACE
TO THE
SIXTH LONDON EDITION.

THE utility of this Dictionary to students and all classes of medical practitioners, has obtained for it in this country a larger share of patronage than was perhaps ever conferred upon any other book of surgery; while its translation into the French, German, Italian, and Russian languages, and several republications of it in America, may be taken as proofs of its being deemed worthy of considerable notice in various other parts of the world. At Milan, one translation of it was produced a few years ago; and I learn from a letter, with which I have lately been honoured by Dr. Cressimbini, president of the Medico-Chirurgical Society of Bologna, that he is preparing another Italian translation, into which he proposes to introduce additional subjects, and such remarks as are founded upon his own researches and experience. The diligent and enlightened Germans were not only the first to undertake and complete a translation; they have bestowed still greater attention upon my humble endeavours to promote the cultivation and diffusion of surgical science; for they have followed up their translation by a series of well-executed engravings, expressly designed to illustrate the nature of the diseases, accidental injuries, and curative methods, treated of in this Dictionary.—(See *Chirurgische Kupfertafeln*, &c. *Wien*, 1820—1829.) Of these valuable plates, the publication of which I regard as an honourable compliment to my surgical labours, nearly fifty numbers have already been brought out at an extremely moderate price; and it is with real pleasure that I recommend them to the notice of every surgeon who is a German scholar, as being the most useful collection of surgical and pathological plates ever offered to the profession.

In preparing this edition, which is enriched with an account of all the latest improvements in surgery, I have conscientiously endeavoured to deal fairly and impartially with every individual whose name I have had occasion to mention, or whose suggestions form subjects of consideration in the ensuing pages. My aim has been truth, wherever I could find her; and in every situation where any glimpse of her beautiful figure presented itself, I have ardently courted her, regardless of the name, school, or country on which she might deign to shed her glory. By steadily adhering to this principle; by zealously marking what the book of nature and the field of experience unfolded; by renouncing all obsequious submission to every other kind of authority; and by taking the liberty of sometimes thinking and judging for myself; I trust that the most likely plan has been adopted of maintaining the character of this book, and raising my own humble reputation.

According to my usual plan, I subjoin the notice of a few things, which were either inadvertently omitted in the articles to which they relate, or communicated to me after such articles had been printed.

[The several additions which follow in Mr. Cooper's preface, for the greater convenience of the student have been inserted in the body of the Dictionary, under the respective articles to which they refer. They will be found designated by the abbreviation *Pref.* affixed to the termination of each.]

SURGICAL DICTIONARY.

ABD

ABAPTISTON. (From *ἀβ*, not, and *βαπτίζω*, immerse, to sink under.) *Galen*, *Patricianus Aquapendente*, and especially *Benardus*, in his *Anatomicalum Chirurgiarum*, are denominated the crown of the uterus, because it formerly had a conical shape, which kept it from penetrating the os uteri too rapidly, and pressing its teeth in the dura mater and brain. While, however, it is admitted by modern surgeons that mischief may be done by letting the same penetrate too deeply, they do not find it necessary to obviate the possibility of such an accident, by using a conical trepan, with which it would be difficult to make any penetration at all; but they guard against the danger, by observing particular rules and cautions laid down in another part of this book. — (See *Thyphloide*.)

ABDOMEN. The Belly. When a surgeon speaks of the cavity of the abdomen, he confines his meaning to the space included within the bag of the peritoneum. Hence, neither the kidneys nor the pelvic viscera are, strictly speaking, parts of the abdomen.

Antiquaries have divided the abdomen into different regions, the terms allotted to which are so frequent in the language of surgical books, that some account of them in this Dictionary seems indispensable.

The middle of the upper part of the abdomen, from the costal cartilage as low down as a line drawn directly across the greatest convexity of the cartilages of the ribs, is called the epigastric region.

The spaces at the sides of the epigastric region are named the right and left hypochondriac or Epiploic-drua regions.

The umbilical region extends from the navel upwards to the line forming the lower boundary of the epigastric region, and downwards to a line drawn across from one inferior superior iliac fossa process to the front of the other.

The middle space, below the last line, down to the os pubis, is named the hypogastric region.

The parts of the abdomen situated on the outside of the umbilical region to the right and left, or laterally with respect to two perpendicular lines drawn from the greatest convexities of the cartilages of the seventh true ribs, are named the ilio or iliac. On each side of the hypogastric region is situated the inguinal region or groin. The whole of the last part of the abdomen has only one technical appellation, viz. the lumbar region or loins.

As the abdomen is the frequent situation of several important surgical diseases; is much exposed to wounds; and various operations on different parts of it are often indispensable; it claims the particular notice of every practical surgeon. One of the most common affections to which mankind are subject, is that in which some of the bowels protrude. This disease is called hernia, and ought to be well understood by every practitioner, who, however, can never acquire the necessary knowledge without being minutely acquainted with the anatomy of the abdomen. In dropsical cases it is frequently proper to tap the abdomen; and this operation, named paracentesis, simple as it may seem, requires more consideration and attention to the anatomy of the parts than many surgeons bestow. — (See *Hernia*, *Paracentesis*, and *Wounds*.)

Abdomen, *Abdomen* of the eye, may take place either within the cavity of the belly, or at some part of its circumference, and may be either of an acute or chronic nature. Women are generally considered more liable than men to *abdomen* in and about the abdomen; the abdomen named *hemorrhoid*, being somewhere treated of, are here considered them *convulsions*. Collections of purulent matter, resembling third whay, and containing inflammatory or clovish fluid, are not infrequently named in

ABD

the cavity of the peritoneum, as one of the effects of inflammation accompanying pleural effusion. — (*Medic. Nat. Med.* t. 4, p. 215; *Lancet*, *Pathologic* Char. t. 1, p. 127, *essentials* 444. See. Paris, 1806.)

In lying in women, abscesses frequently form between the abdominal viscera and the peritoneum, especially just above the groin. They are cases which have been very correctly described by *Cruikshank*. Before the integuments proper, the diagnosis is often attended with difficulty, and sometimes an abscess penetrates several weeks; for the patients seem as if affected with slight cold pains, which yield to common treatment, particularly external applications, but soon return. Thus, unless the vicinity of Poupart's ligament be carefully examined, where some partial point, hardness, or elevation can be detected, the abscess may remain concealed until a large progression, or the extension of the matter down the thigh, lameness, &c., makes the nature of the case completely manifest. As the peritoneum adjoining the abscess is always thickened by the preceding inflammation, *Cruikshank* assures us that there is no danger of the collection of matter bursting inwards. Some abscesses, indeed, have been so enormous, that the matter actually pushed the viscera out of their places, yet all this happened without any forward bursting of the disease. The whole danger depends upon the direction of the abscess and the extent to which the matter spreads. A timely detection of the nature of the case, the use of resolute applications, and the making of an early opening, generally being the disease to a speedy and favorable termination. — (See *Agnew's Magazine* for the *Wanderer*, *Wanderer*, *Wanderer*, &c. t. 1, p. 173, Nov. 1807.)

Chronic tumors of the os uteri, which in women are stilling sometimes terminate slowly in suppuration, and fluxion of the os uteri and other abdominal viscera, leading to the formation of matter, are often the cause of painful menstruation, great sensitiveness, hortic symptoms, and death. However, sometimes salutary abscesses are produced between the viscera, by which means an outlet is obtained for the matter through the bladder, anus, or vagina. Thus (*Journal* *Lancet*) in the case of a woman who had had for a long while pain in the right iliac region, exposed to proceed from suppuration of the kidney, because pain was united with the urine; the right kidney was found after death in the natural state; but there was an abscess in the right ovary, which was adherent to the bladder, and which the pus had passed through an ulcerated communication. In another patient, who had voided pus by the anus, the right kidney was exposed and adherent to the colon, with which it was communicated by a perforated aperture. For many years a woman had a hard tumor of considerable size in the abdomen; at length the pain of it became insupportable; and just at the moment when her death was apprehended, an immense quantity of pus was cut, duly discharged from the vagina. The pain abated, the swelling of the belly subsided; merely the remains of the inflammation were any perceptible; and the woman's health was perfectly re-established. — (*Lancet*, *Pathologic* Char. t. 1, p. 128.)

The abscesses which sometimes form between the peritoneum and abdominal viscera, or between the layers of these viscera, or under the integuments of the abdomen, are attended with considerable misery, according to they happen to be divided or acute, circumscribed or diffuse, small or extensive. Those of the acute or phlegmonous kind, sometimes following stabs and contusions, are particularly noticed in the article *Wounds*. There are those which demand especial care, because if not checked they may prove

adhering to the liver, pancreas, and abdomen; and a coarse jagged beginning its internal surface from the diaphragm to the insertion of the esophagus, the coats of the stomach being an inch thick. The surface of the pancreas was also diseased, and the pylorus, situated in the middle of the cancerous mass, was contracted by the thickening of the process of the stomach, and obstructed by numerous fangs. The liver was large, but apparently sound; the spleen small. The aorta, the vena cava, and its branches, were quite natural.—(*See Journ. de Med. par Leroux, Oct. 1835, and Medico-Lir. News, vol. 3, p. 295.*)

Morgagni describes the case of a woman 34 years of age, who, after a suppression of the menses for some months, was attacked with palpitations in the epigastrium. Morgagni, on applying his hand to the part, felt a large hard body moving freely. At first, it was regarded as an aneurism of the phalanges; but, as there were no arterial throbbings in the chest, and there was nothing extraordinary in the pulse at the wrist, Morgagni concluded that the tumour in question could not depend upon the heart. Neither did he take the disease for an aneurism, because the throbbings did not correspond to the base. As for the large indurated mass, it appeared to him more like any what it was not, than what it was; it could not be named a glomus ageritum, which never looks like an aneurism. Morgagni considered the case as an hysterical spasmodic complaint, ordered the patient to be bled, and the 54th leaving the palpitation ceased.—(*Morgagni, de Anomal. de Causis Medorum, t. 2, Epist. 30, 25.*)

Senac has spoken of these abdominal palpitations as occurring in hypochondriacal and hysterical patients; and, as they frequently subside without leaving any vestige behind, he sets them down as nervous affections.—(*Traité des Mal. de Cœur.*) Dr Hays had under his care a hypochondriacal patient, affected with palpitations in the abdomen; which, with other complaints, were relieved by doses of liver opening medicines.—(*Hollings, Medical, Therapeutics Plain and Easy, 1792, t. 2, p. 21.*)

Thalheim observed a distention of the stomach, which he supposed to have been epistemic and glandular, in some persons, with palpitations in the epigastrium cordis.—(*Med. Lib. Newark, Pars 1, 1793, p. 211-277.*) My friend Mr. Hodgson, also, in speaking of palpitations in the epigastrium, which are the consequence of organic disease, and occur in irritabile hypochondrium acutum, states his opinion, that, in some instances, these palpitations were a consequence of distention of the stomach with air, which was thrown against the abdominal muscles by the pulsation of the great blood vessels; and in such cases, the throbbing was distinguished by the sensation.—(*On the Distention of Arteries and Veins, p. 96.*)

Abdominal palpitations are also described by Zedler, as a symptom of hypochondriasis and hysteria.—(*De Hypochondria, Lips. 1799, p. 78.*) They also happen in certain Schizoid diseases.—(*Traité des Mal. du Panchyphage and des Mésentériques, par C. G. C. Brasseur, Lips. 1795, p. 21; and Dr. R. Jackson in the Memoirs of Jackson, Med. Lond. 1798.*)

In a dissertation on cramp in the stomach, Hall remarks, "Quin insidit, uti distans vesicæ gastricae, contritus agrotant perenni spasmus, ut ei haud raro prominentes tumores plenis, dilatatis, in cordis et ventriculi, pulsi externi cordis maxime videntur."—(*Thes. de Gastroscopia, Opuscl. 120.*) In the same essay, there is an account of a man, who had violent palpitations in the epigastric region, apparently first excited by the larva of the tinea probably, many of which were vomited up.

Paul is another writer who describes these abdominal palpitations as an occasional symptom of hypochondriasis. "Palpitationes de vena et gastropneumone sunt, de palatione irregulata, sine ullaque parte de viderentur."—(*Nouveau Philosophique, t. 2, p. 25, Paris, an 6.*)

Dr. Albert details some cases which fell under his own notice. A young woman, whose menses were open but, and who had been for some days constipated, was seized with frequent fainting fits and stertile apnoeas, occasionally ending some the bowels a quantity of black matter, each evacuation of which was followed by a storm, the vomiting at five o'clock Dr. Albert was sent for, as it was found the patient was about to die. She was extremely exhausted, and

the fainting fits followed each other with hardly any intervals. She could just say "I feel a throbbing in the belly;" and, when Dr. Albert applied his hand to the part, he felt a violent pulsation extending from the umbilical hernia down to about the bifurcation of the aorta. The action of the heart was weaker than natural; the pulse at the wrist very small, but not quicker than it had been in the preceding day, and not synchronous with the throbbing in the abdomen. Dr. Albert concludes, that, at first, he took the case for an aneurism. Dr. Marshall was of the same opinion. Another physician, however, Dr. Wenzel, ascertained doubts of the aneurism being aneurismal, saying, that he recollected having read, several cases in Morgagni. These doubts seemed to persuade in the employment of opening medicines and clysters, continuing again with the former. Under this plan, the palpitations in the abdomen and fulgencies of the chest diminished in a few days. The stools were at first of the colour of chocolate, but afterwards possessed their natural appearance. The vomitings, in a weakened form, however, were perceptible six weeks longer. The patient at length got quite well, and was remaining so four years afterward.

A man about 40, severely afflicted with hypochondriasis, great oppression of the chest, constipation, and tension of the abdomen, tendency to fainting, &c., complained to Dr. Albert, that he felt as if his heart had fallen down into his belly, where he was annoyed with an increased throbbing. Indeed, when Dr. Albert examined the abdomen, patients he could feel a very strong pulsation, and, what is curious, could trace it like a cord along the track of the aorta, but in the course of the left iliac artery. The pulse at the wrist, which was small, frequent, and hard, did not correspond with the abdominal pulsations. For several days the aneurism from the bowels had been as thick as pitch. After the employment of gentle purgatives, all the complaints gradually abated, though the throbbings were fully perceptible six months afterward.

The next case which Dr. Albert met with is very interesting. A robust sailor, whose bowels were so constipated, that nearly the strongest purgative could affect them, was seized with constant pain in the left hypochondrium. With this complaint was soon joined great pain in the back, and a sensation as if something alive moved about in the belly from one side to the other, and thence extended up to the neck, followed by the vomiting of a greenish matter. At the same time, he felt in the left side a pulsation which he took for that of the heart, and which continued the whole of his illness. The pulse at the wrist was natural, and synchronous with that in the abdomen. In the beginning of the disease, the patient was obliged to sit with his body very much inclined forwards, as no other posture could be endured. For the first week opening medicines afforded no such relief, that he was sometimes quite free from pain for six or eight hours. After a time, a round swelling formed in the left hypochondrium, reached to the navel, and attained with incredible quickness the size of a child's head. Indeed, it could now be traced beyond the umbilicus to the right side. The venous were quite of a dark colour, or else red blood and a puriform matter were discharged. Sometimes the blood voided was of a bright red colour, sometimes it was dark, coagulable, and mixed with bile. The patient was at length worn out with febrile symptoms, and died. On opening the body, Dr. Albert found a swelling in the middle of the mesentery, the texture of which cannot be easily described, and the circumference of which was 16 French inches. The stomach was filled with coagulated blood. The spleen, pancreas, and liver were sound; but the gall-bladder was of prodigious size, and contained thick viscid bile. The aorta contracta, aorta cœliaca vasa, and the aorta mesenterica were postmortally dilated, and full of dark-colored blood. He speaks of them, however, only as being in an enlarged, not in an aneurismal state. Dr. Albert thinks it highly probable, that it was one of these vessels by which the pulsation had been communicated.

Dr. Albert has also seen these abdominal palpitations in a pusillito female; and in a healthy, who was afterward seized with apoplexy. He likewise met with a violent tremor, the mother of several children, in whom these throbbings took place incessantly at the commencement of each menses, and were a source of

of this may, that other common effluvia, as stoppage of the menses, &c. After the third month, however, they tend to cease altogether.

Many valuable practical observations on cases attended with hæmorrhages from the intestinal canal, my limits here oblige me to pass over. According to Dr. Albers, hæmorrhoidal patients, especially when put in motion, are by compression of the tumours, often sensible of throbbings about the anus, which are paid even to the hand.—(J. F. Albers, *over Polypus in the Intestine*, *Ver. Drukker*, 1833.)

Dr. Parry makes a few interesting remarks on such abdominal pulsations as evince compression of an artery. In any person, not very fat, and lying upon their back, he says, the pulse of the aorta can easily be felt, if strong pressure be made a little to the left of the median line, about half way between the navel and umbilical cord. In certain instances, the pulsation is perfectly felt by the patient himself. In many cases of this kind, particularly in females, individuals, the sense of pulsation is merely the effect of premenstrual action of the heart. While, in other cases, it is the effect of the pressure of some hard substance upon the descending aorta, determining a disproportionate quantity of blood to the head, "and pressing to the head passed on the abdomen, and sometimes even to the eye, the appearance of a beating so near the surface, as to lead inexperienced observers to conclude, that the vein is greatly dilated." According to Dr. Parry, the most common causes are obstructions of flow in the aorta, requiring repeated and active purgatives, which must bring away almost incredible discharges of mucous and watery matter before the arterial pulsation subsides.—(See Parry's *Elements of Pathology*, &c. and the *Medical Clin. Journ.*, and *Review*, vol. 1, p. 37.)

Another cause of a temporary appearance of pulsation or movement in the abdomen, not sustained by any of the preceding actions, is the power which water persons have of putting portions of the rectum in motion, and thus strong convulsive action. There seems a large absorption of the lutea stimulated with distasteful and fecid pulsations, corresponding to those of the aorta.

According to Mr. Allan Burns, a beating is generally felt about the pit of the stomach, in the advanced stage of chronic inflammation of the heart; in this case, when the pulsation is closely adherent to the lateral epigastrium, it is corrupted at every contraction of the ventricle, and the diaphragm and liver are elevated. The ventricle, however, having completely emptied itself, is again diminished, and is propulsive to the degree of dilatation, the liver and diaphragm descend, whereby an impulse is communicated in the epigastric region.—(See *Diagnosis of the Heart*, p. 293.) This valuable writer cites the remark of Morgagni (*Epist. 17*, art. 26), that sometimes, in dilatation of the heart, this organ descends so far as to push the diaphragm into the hypochondrium, and pulsate in that situation, so that the disease is sometimes for a moment of the cellular artery. In Mr. Burns's work, a remarkable case of this description is related. An erroneous judgment in the case lately is to be formed in such cases, because the pulsations of the heart and lungs are not exactly synchronous; for it is not the heart which is felt directly beating, but the liver, which, by the action of the heart, is thrown forward. Hence the pulsatile interval between the stroke of the heart and the movement of the liver.

The following fact shows how dangerous a practitioner should be in the progress. An extraordinary vessel arrived at, that he assumed a pulsation, in confirmation with all systems, vapour and incense as means, where the most dangerous pulsations of the liver, and such pulsations between the epigastrium, were swift symptoms. The pulsations could be both seen and heard at a distance, on resting the arm in which the patient sat. Several physicians were induced to suggest some organic lesion of the internal system; but their opinion was given with becoming diffidence.—on the surgeon's, his impression was, that there existed an aneurysm of the descending aorta; and such was the firm persuasion to him acquired of the reality of his impression, that he could trace the aneurysm as through the abdominal coverings, though nobody else could, and trace its magnitude and position. After death, the heart was found enlarged, and pit full of venous of enormous size. The liver was

of the stomach also exhibited traces of long existing disease; but the aorta was quite sound.—(See *Med. Juridica*, 1821, p. 71.)

Preternatural pulsation about the epigastrium is also stated by Mr. A. Burns to be sometimes occasioned by enlarged tumours, attached either to the upper surface of the diaphragm, or formed between the layers of the pericardium towards the diaphragm, as happened in an instance recorded by Lennet.

Another cause specified by Mr. A. Burns, is enlargement of the vena cava, or of the right auricle of the heart. Now describes a case in which the vena cava was as large as the aorta, and there had been a violent pulsation in the epigastrium.

The next cause enumerated by the same gentleman is increased solidity of the lungs, more especially of their lower acute margins, where they overlap the pericardium. In this case the pulsation is about the epigastrium cordis.

Mr. A. Burns likewise notices several other causes of epigastric or abdominal pulsations, already illustrated in the foregoing part of this article, including the pulsations, sometimes of the pylorus, tumours in the mediastinum, or any solid increase of substance about the abdominal aorta, or its principal branches; and, lastly, a peculiar affection of the vascular system itself.

The following observations on the criteria between various abdominal pulsations and those of aneurysms, appear interesting.

According to Dr. Albers, an internal aneurysm originates gradually, and the pulsations increase in strength by degrees. Other abdominal pulsations, on the contrary, begin suddenly, and are most violent in the beginning, abating after they have lasted some time.

In an aneurysm, the pulsation is synchronous with the stroke of the artery in the wrist; but this is not regularly the case with other pulsations.

Should the patient be affected with melancholia, hypochondriasis, hysteria, or other nervous complaints, void blood from the stomach, or a black vomit from the bowels, should there be any hæmorrhage or swelling of any of the abdominal viscera discoverable by the touch, the probability is, that the pulsations are not owing to an aneurysm.

With the exception of cases in which these pulsations are owing to mechanical impediments in the circulation, Dr. Albers believes, that they are nearly a symptom of some nervous affection. He also thinks, that the surprise excited by these throbbings arises only from their strength and duration, other analogous strong pulsations, as, for instance, those of the heart, or of the carotids being common enough in hypochondriasis and hysterical persons. The same gentleman adverts to the increased action, which, in inflammation and fever, is often more conspicuous some parts of the sanguiferous system, than in others.—(See *Pulsations on the Epigastrium*, p. 20, &c. *Albers*, 1833.) Much important additional information on this subject may be found in *Observations on some of the most frequent and important Diseases of the Heart; on Aneurysm of the Thoracic Artery; on Preternatural Pulsation in the Epigastrium*, &c. by Allan Burns, p. 292, &c. *Edin. Edinb.* 1833.

ANEURYSM. A tumor containing pit, or a collection of purulent matter.

Aneurysms are divided into two principal kinds, true, acute and chronic. For information relative to the former, see *Aneurysm*; and for that concerning the latter, refer to *Lancet Disease*. See also *Chronic Aneurysm*, and *Dissection of the Epigastrium, Hypochondrium, Mesenteric Artery*, &c.

ANISOTROPHIA. That nature has fully provided for the due evocation of this important function, is a truth of which no doubt is entertained; it must be immediately exhibited to every person who reflects upon the instance which is continually taking place in the particles of every texture of the animal body; upon the gradual and harmonious removal of the old matter in proportion as the new is deposited by the ascending arteries; or upon the impossibility of accounting for the changes produced by growth in the old and young of different organs, and, indeed, of the whole body, without consciously bringing into the explanation this important process, of which nature and even the most essential particulars, is a true, yet remote discovery. But, besides these considerations in proof of anisotrophia, many others exist which the sci-

explanatory physiologist. By the action of the absorbing and exhalant arteries, the whole mass of blood would soon be so impregnated that life would be irretrievably gone, if the sanguiferous system were not daily replenished in some way or another. The undiminished quantity of blood in the circulation, notwithstanding the constant exhalation from it by secretion and excretion; the regular fulness of the blood-vessels, notwithstanding the incessant drains from them; and the constant supply of materials for the sanguiferous functions; all imply the existence of a certain function, one principal design of which is to counteract the effect which, without it, would be rapidly and fatally produced upon the quantity of blood in the system. As M. Magendie observes, whenever any substance in the form of a liquid, gas, or vapour, is put, for a certain time, in immediate contact with an external or internal surface of the body, it is absorbed; that is to say, it passes into the blood-vessels, mixes with the blood, circulates with it, and thus exerts its effect directly or indirectly upon the viscera. This is particularly exemplified in the action of certain poisons; a drop of pure hydrocyanic acid, put on a dog's tongue, causes the animal's death in a few seconds, in consequence of being immediately taken up by the blood. Food, drink, medicines, and even air itself, only because useful to us, after having been absorbed. Many diseases, some of a very dangerous kind, are originated by absorption. In fact our existence is so inseparably connected with the function, that the suspension of it for a moment would produce almost immediate death.—(See *Journ. de Physiol. Expér.* t. I, p. 1.)

The office of the absorbents, as a modern writer has remarked, is naturally expressed by their name; it consists in receiving or taking up certain substances, and in transporting them from one part of the body to another. The substances which are thus taken up, are of two kinds, first the food and the breath; the former being received by the lacteals, and the latter by the lymphatics. The immediate object of the action of the two sets of vessels, is, however, also essentially different; that of the first being to convey a food from the part where it is formed into the blood, in order that it may directly serve for the nutrition of the body; the latter serving, in the first instance, to remove what is useless or hurtful, and to discharge it as such a system, that it may either be applied to some secondary purpose of utility, or be finally discharged from the system.—(Bainard, in *Klin. Syst. of Physiology*, vol. 2, p. 551.)

The laws of the absorbent system are far more intricate than would at first be supposed by a person only superficially acquainted with physiology and the phenomena of disease. If we wish to form a just comprehension of all the various purposes which this system fulfils in the animal economy, we must take the same enlarged view of the subject as Mr. Hunter did. We must contemplate all the modifications of absorption, and its effects both in health and disease, in the nutrition and growth of the body; as well as in the excretion, or absorption, and the dissolution, or even final removal, of parts of it, become diseased or useless.

First, According to Mr. Hunter's explanation, the absorbents take up extraneous matter, in which is included nourishment.—(On the Absorb., &c. p. 484.) By extraneous matter we are here to understand matter not originally contained within any portion of the body, nor constituting any part of its natural structure, but introduced from without. Thus the absorption of nourishment, absorbed pus, coagulable, and other substances applied to the skin, furnishes examples of the absorption of extraneous matter, which are also attended by the effects of the venereal, syphilitic, vaccine, and several other poisons. Sometimes the passage of the poison into the system and its pernicious operation, happen so rapidly, that symptoms are manifested that it must have a shorter course into the circulation than through the lymphatic vessels, the glands, and trunks. This has been supposed to be the case when animals are filled with hydropicous fluid, the venous trunks, the points of contact, the spine, &c. How far this system is true will be hereafter considered. Such is the simplicity with which the poisons of typhus fever, scarlet fever, and the ligament's head are absorbed and carried into the sanguiferous system, that in twenty seconds after being put into the cavity of the panto-

mean, their action reaches the spinal marrow.—(See *Magendie's Journ. de Physiol. Expér.* t. I, p. 18.)

Secondly, As Mr. Hunter has noticed, the absorbents take up superfluous and extraneous matter, whether natural or diseased. Thus, the removal of the old particles of the body, after they have become unfit to continue longer in their respective situations and offices,—an action that is reciprocal with the deposition of new matter by the secretory arteries; and the incessant regulation of the quantity of serous fluid in the cavities of the chest, chest, peritoneum, and tunica vaginalis, so that, though the arteries incessantly secrete this fluid, the absorbents prevent its extraneous accumulation, and combine with the blood-vessels in maintaining a continual renovation of it; are examples of the absorption of natural, but superfluous matter. On the contrary, the disposition of extraneous blood, of the fluid of serous and mucous, of coagulable lymph, or air, effused in the cellular tissue, and of an infinite number and variety of exudates and thickening of parts; are instances of what Mr. Hunter has termed the absorption of superfluous, diseased matter, or, as I should say, of superfluous matter from disease.

Thirdly, Mr. Hunter enumerates the absorption of the fat. No doubt can exist respecting the collateral changes which are taking place in the quantity of serous matter in the body, according to the state of the health, the nature of various labours, or labour to which the body is exposed, a diseased or debilitated condition of the vessel, and the effects of different kinds of regimen and diet on the whole system. Perhaps it may be supposed that Mr. Hunter should distinguish this absorption from that of other superfluous matter in the body. The reason does not appear in his writings; unless we receive as such the observation, that he did not consider the fat and matter of bones as true animal substances, as they have no action within themselves and are incapable of life. However, this would not be very consistent, because other superfluous matter, composed in the second classification, especially the fluid secreted by serous membranes, and the fluid of nutrition, are likewise superfluous parts of the living principle. At the same time I admit that the absorption of the fat may be entitled to distinct consideration on other grounds; for sometimes an absorption seems to be regarded as a much greater degree than that of other substances in the body; or at all events its absorption does not keep pace with that of its secretion, so that, although the trunks and other organs remain of their usual bulk, the fat may acquire the thickness of several inches. On the other hand, the absorbents sometimes act upon it with a quickness that does not always extend to the same term in other parts of the body. Thus in fever nearly all the fat may be absorbed in the course of a few days; yet the size of the muscles may have undergone but little reduction.

Fourthly, Mr. Hunter enumerates the species of absorption by which a waste of parts is produced, and is consequent of which the muscles become smaller, the bones flatter, &c. These cases we first exemplified in the ordinary course of nature; for in old age such changes happen in the bones and muscles, and also in other organs like the absorbent glands, which become so diminished, that some writers erroneously assert that they entirely disappear. Whenever the action of a vessel is long prevented by disease of a joint, a fractured bone, or other causes, it always dissolves away to a greater or less degree, and the limb compared with the sound one will be found to be considerably reduced. The absorption of the fat, by which the bulk of parts is also lessened under various circumstances of disease, I believe is not generally restricted to a particular liver or joint, like the absorption which affects the muscles in similar cases. Thus, when a patient becomes thinner than disease of the hip-joint, the muscles of the thigh and leg on the same side as the disease undergo a remarkable decrease of their bulk, while those of the sound limb are little or not at all altered; but the fat of the whole body is rapidly absorbed, and the greatest natural emaciation prevails.

Before the period of Mr. Hunter's writings, the knowledge of all the different purposes of absorption, by whatever organs it was supposed to be performed, whether by lymphatics or veins, was certainly very limited in comparison with the more extensive in-

formation which now permeate, and which is in a great measure the fruit of his industrious researches. Speaking of the absorbent vessels, which he considered, with the generality of modern physiologists, as the true instruments of absorption, he says: "From a further knowledge of these vessels we shall find that they are of much more consequence in the body than has been imagined, and that they are often taking down what the arteries have built up; removing waste organs, forming a modification of the form of the body in its growth, and removing many diseased and dead parts, which are beyond the power of cure."

As these vessels are productive of a great variety of changes in the animal economy, which are very characteristic in their structure and effect, Mr. Hunter considered them in two general points of view: first, as they absorb matter, which is not any part of the body itself; secondly, as they absorb the body itself. The first of these uses, the absorption of matter which is not part of the structure, he observes, is well known, and of two kinds; first, that of extrinsic matter, comprising every thing applied to the skin, and also the chyle; the other internal, comprising that of many of the secretions, the fat, the milk of bone, &c. These kinds of absorption take place principally for the two purposes of the body; but they also answer other purposes, and are very extensive; for, besides their nutritive effects, they are frequently the cause of disease in a thousand forms.

In the second of the above-mentioned views, Mr. Hunter considers the absorbents as removing parts of the body itself, and here he again views them in two lights. The first is where only a wasting is produced in the whole body or some particular part of it, to which mode of absorption he applies the epithet *atrophic*, because it consists in the removal of particles of the body out of the substance of parts which yet remain, and still form a perfect whole. This kind of absorption, Mr. Hunter says, has always been admitted or supposed, whether performed by the sense of disputation. It is often carried further than the mere wasting of the part; for it may proceed till not a vestige of such part is left, as is sometimes complained of in the total decay of testicles. *Interstitious absorption*, therefore, may be understood in two senses.

The second view taken by Mr. Hunter embraces that kind of absorption by which whole parts of the body are removed, and which is sometimes a natural, sometimes a diseased, process. "It is a view of which he particularly values the discovery. In the natural process he says, the absorbents are to be considered as the modifiers of the original construction of the body. No absorption can take place in the natural formation of many of the parts, either in the natural growth or the formation arising from disease, without the action of the absorbents, which always have a considerable share in the production of the changes. Thus in three modeling absorptions, the principle of which is an extensive as may be the natural process, bones and squamous other parts cannot be formed without it. A part which is of use in one stage of life, but becomes quite useless in another, is thus removed, as is exemplified in the decay of the eye, the ducts of the prostate, and the squamous prostates. In some cases the absorption of whole parts in consequence of disease leads to dissolving effects; one is a case in silver, and Mr. Hunter therefore calls the process by which it is produced, *dissolving absorption*. In other cases it is called, although whole parts are removed. Such three forms of absorption, he thinks, may be named *progressive*.

The removal of a whole solid part of the body, or as Mr. Hunter expresses it, "that portion which the animal economy has taken a part of itself into the circulation, by means of the absorbent vessels, whenever it is necessary," is unquestionably one of the most curious facts which can present themselves to the notice of the physiologist (nature). In Mr. Hunter's time the doctrine was a new one, but he informs us, that he had long been able to demonstrate its truth, and that he possessed the first facts of it from the waste of the secret of the teeth and of their fangs at the period of their being shed.

It may be difficult at first to conceive how a part of the body can be removed by itself; but it is just as difficult to conceive how the body can lose itself, but they are both equally true. Without dwelling on the exact mode in which such changes happen, he gives a

new idea, that "whenever any solid part of our bodies undergoes a dissolution, or is broken in upon, in consequence of any disease, it is the absorbing vessels which do it."

"When a business necessary, that some whole living part should be removed, it is evident that nature, in order to effect this, must not only render a body sensitive on the absorbents, but must direct the part to be absorbed into such a state as to yield in this operation."—See *Hunter on the Blood*, &c. p. 420—442.) For an account of *arterial absorption*, vide *Circulation*.

With regard to the difficulty which there may be in comparing how each small vessel in the lymphatics can take up solid substances, Bichat points out that the distinction between the solids and the fluids can only be said to prevail where they form a mass; but that when reference is made to their separate particles, they do not differ from each other. This, he says, is so perfectly true, that the very same particles will alternately enter into the composition of a solid and a fluid, and as the elements of water are the same, whether it be in the liquid or frozen state. Now as the transportation of solid substances takes place by the removal of these separate particles or atoms, no greater difficulty can present itself in understanding how this may be effected, than in conceiving how fluids may be absorbed. —See *Hunt. Gen. & Sp.* 52.

I come now to a very difficult question, and one that has hitherto received no satisfactory answer; not because the subject has not been exhaustively deeply, and ably considered, but because its difficulties and obscurity seem to defy all successful investigation. The question here referred to is, the most principle and by what power is the lymphatic, supposing them to be ascertained glands, enabled not only to take up the solid particles of various organs and different fluids secreted in different features and cavities, but to convey them frequently with considerable velocity and through a long tract, dispersed also by these complicated organs, the absorbent glands, into the venous system and the heart? In other words, what is their mode of action? As Mr. Hunter has observed, the principle of capillary action was at first the most general idea, because it was familiar one; but this is too confined a principle; for still it is a reason for every kind of absorption. Capillary action can only remove fluids; but as solids were often absorbed, such as fine tumours, coagulated blood, the art of others, &c., he advances for this hypothesis more completely to suppose the existence of a solvent.

"That any one may not be misled; it is one of those hypotheses that can never be proved or disproved, and may for ever rest upon opinion." But Mr. Hunter's conception of this matter was, that nature leaves as little as possible to chance, and that the whole operation of absorption is performed by an action in the vessels of the absorbents; but even under the idea of capillary action, physiologists were still obliged to have recourse to the action of those vessels to carry the lymph altogether if it had been absorbed; and they might as well therefore have extended this action to the mouths of the vessels.—(See *the Blood*, &c. p. 442.)

The question will continue without satisfactory answer, whether Hunter's language be adopted, and we say that absorption is effected by an action of the lymphatics and their outlets; or whether we employ the language of Bichat, and ascribe the performance of the functions of these vessels, and the circulation of the fluid in them, to what he is improperly (but not much to the detriment of his reasonableness) ergone sensibility and sensibility organic contractility. This assumed kind of sensibility arises from every adjacent vessel a power of feeling quite unconnected with the brain, by which it is presumed to be sensible of the presence of matter in its current, which is then imbibed and conveyed along the tube by the insensible organic contractility, by which is signified a power of contraction, not admitting of dissolution, but capable by stimulus or irritation, but without to take place in some insensible manner, chiefly because the fluid in the absorbents is known to be constantly in motion, and always flowing towards the thoracic duct. In fact, Bichat's explanation is merely a reference to two principles, which are themselves hypothetical, and more calculated to excite a playful fancy than to satisfy a sound judgment. Organic sensibility, and insensible organic contractility, he observes, are the

were remarkable in the absorbent system, as they were for a certain time death itself. A dead, exposed while the animal retains some degree of heat, is absorbed both on serous and mucous surfaces, and also in the cellular tissue, though with less freedom. This power of absorption after death, he says, may even be ascertained by keeping the artificial lung by means of a bulb, though the plate is less efficacious than in a first supposed, vital heat seeming to be essential.—(*Lect. de la Vie*, t. 2, p. 117.) All these observations, however, merely amount to a recital of the facts, that absorption may proceed for a short time after death (never later than two hours from this event, p. 115.), and that it is promoted by artificial heat; but how, or by what exact mechanism it is accomplished, is not revealed to us.

The lymphatics are not regarded by Richi as aided either with wind to form animal elasticity, or with animal contractility. His proof of the fact of these matters is, that when a lacteal vessel, full of chyle, a lymphatic filled with serosity on the surface of the liver, or even the thoracic duct, is interrupted, the animal suffers no mark of pain. But this tells him which the lacteal put in the stomach may be expected from the question to which it leads him, namely, What influence can be derived from a circumstance which, in consequence of the belly being laid open, the many openings produced would necessarily admit of air slight ventilation, even were it to exist? He also adverts to the little sensibility of the absorbent vessels in their interrupted state.—(P. 118, &c.)

He also alluded to a vital contractile property in the lymphatics, or, as Richi would express it, sensitive organic contractility. The former adopted this belief, because these vessels readily empty themselves of the chyle that is pervading them, and contract when sulphuric acid is applied to them. On the other hand, Richi argues, that sulphuric acid, like every other concentrated acid, will also kill, produce the same effect upon all animal substances, even after death, as well as a striking of them. When the absorbents, and particularly the thoracic duct, are touched with the point of a knife, they do not contract. If they are capable of contraction, Richi maintains that it is when they cease to be distended; and not when they are injured; consequently, it appears to him to be by virtue of their contractility of tissue. The opinion of which he finally arrives at, that sensitive organic contractility in them is at all events doubtful, and that, if it exist, it is very obscure, and at most not proper than that of the lacteals.—(P. 9, p. 115.)

This last inference, and, indeed, the whole of Richi's notions respecting the non-existence of sensitive organic contractility in the absorbent vessels, are very difficult to reconcile with certain observations made by himself, in other parts of his work. Thus, he observes his spleen (t. 2, p. 98), after he had frequently noticed in living animals, especially in dogs, manifest expansions in the course of a lymphatic, and containing a liquid fluid. These appearances were mostly met with on the external surface of the liver, and on the gall-bladder. When the distended portions of the vessel were touched with a needle, the fluid ran out, and they immediately disappeared. "On another occasion, I saw two or three of these small dilatations on the gall-bladder, and having then lit the lamp directed with a torch under the vessels, I saw each dilatation the next instant at not being able to find them again: so doubt says he, the contraction of the vessel had made them disappear." He adds, that the liver is the organ on which these vessels can be best seen in living animals; but its convex surface must be looked at the instant the belly is opened, for the contact of air, by making this contact, then follows their free escape through it.—(See *Ann. t. 2, p. 98*.) And in another place he says, "It is in dogs where the absorbents are full, if the skin be lifted up, they may easily be distinguished by their transparency; but very soon, notwithstanding their valves, they empty themselves, and can no longer be distinguished from the rest."—(P. 108.)

The fact of the absorbents expelling more or less of their contents, when they have been produced, might be very well ascribed to what Richi calls contractility of tissue, or even to elasticity; but, the propulsion of the fluid from a dilated portion of an uncontracted lymphatic into another portion of the same

vessel, certainly does not admit of the same explanation. The valves may determine the direction which such fluid must follow, if it move at all; the anastomoses may facilitate the progress of it; and contractility of tissue, or elasticity, may have an auxiliary effect; but its first motion can only be accounted for by supposing either that there is an impelling power in the vessels themselves, or in some organ or organs with which they are connected; or else that these contents are set in motion by external pressure, the vessel of vessels is within, or the pulsation of neighbouring arteries. Now, in some of the cases mentioned by Richi, no doubt can be entertained that the impelling power was in the lymphatics themselves, because he distinctly adverts to the contraction as speedily excited in them by exposure to the air, that the convex surface of the liver must be looked at immediately on the animal's belly being opened, or else they will not be distinguished.

Dr. Haigack contends, that "an attraction exists between the mouths of the lacteals and the chyle, which seems to be analogous to, or identical with, the elective attraction, which causes different chemical substances;" and "that the lacteals, as well as their extremities as they enter their whole extent, are possessed of contractility, by which the fluids, when they have once entered, are propelled along them; an effect which is probably generated by the pressure of the neighbouring parts, while the anastomosing valves with which they are furnished prevent the retrograde motion of their contents."—(*Ann. de la Vie*, t. 2, p. 101.) The principle on which the lacteals receive the chyle can scarcely be referred to any thing so fixed and determinate as chemical attraction, or so independent of life. On the contrary, the absorption of chyle from the lacteals may be delayed, or accelerated, or retarded, by various means of the combination, balance of life, and different altitudes of the mind. If it were a chemical operation, and the absorbence of chyle supposed to exist on the valves out of the vessel, motions, in the period of any sudden depth, the process would be expected to go on as long as that fluid and the still retained in contact; yet we have no proof of this being the case; indeed, I must, I suppose, say something between electro-attraction and the absorption of chyle; the former being an operation in which the action of vessels at their orifices, and the influence of life, are considerations totally separated from the subject; whereas, in the latter, they form in reality the main topics of inquiry. Elective attraction, however, may only be ascribed as a comparison applicable to the disposition which the lacteals have to take up certain substances, but to reject others, though even in this sense, the comparison would be very imperfect.

Dr. Haigack's opinion is probably true, that an stimulation of the action of the lymphatics must be attended with even greater difficulty, than what persons meet with in the inquiry into the principle on which the chyle is taken up and conveyed into the system. The increased difficulty chiefly proceeds from our having no positive information respecting the contraction of the lymphatic vessels, or the mode in which their contents are first received; "for there is reason to suppose that the transmission of the fluids themselves is conducted upon the same plan with that of the lacteals." As the same author remarks, we do not know where the mouths of the lymphatics are situated, with what parts they are connected; how they are brought into contact with the substances which they receive; nor by what power they are enabled to take them up.—(Vol. 1, p. 101.)

The source of the lymph is also less certain than that of the chyle; for, even at the present day, Dr. Haigack, influenced by the possibility of directing the lymphatics from the arteries, and by the anatomical nature of the lymph, and its analogy to the blood, presumes a belief, which was certainly many years ago, that it is not formed by the decomposition of the solid particles of the body, nor by fluids absorbed from various surfaces; but that it is composed of the thinner parts of the blood, which, instead of returning to the veins in the heart, pass into the lymphatics, and are conveyed to that organ through the thoracic duct. The lacteals certainly have little disposition to take up any thing but chyle; but, as Dr. Haigack has explained, "the lymphatics are capable of absorbing a great variety of substances, differing from each other most

widely in their nature, so that it would almost appear as if, by a certain mode of operation, any substance might be forced into them. Nor (says Dr. Bantock) is this distinction affected by the hypothesis of M. Magendie; for, although we might agree with him in expecting that in the ordinary operations of the system, the force at the principal, or even the most instantaneous, in removing the materials of which the body is composed, yet we have no experimental evidence, that when certain processes or medicinal agencies are applied to their introduction, they may be forced by force into them, and conveyed into the circulation. The case of pus, or other medicinal substances that are taken up by the lymphatics, may appear to be less difficult to explain, because the absorption is generally produced by fibrils, or some mechanical process, which may be supposed to force the substance into the vessels of the system, or to produce its escape from the capillaries, which may enable the substance to come into some immediate contact with the vessels of the vessels. We may also imagine that when the component parts of the body are brought into close approximation with their capillary extremities, they are then taken up in the same way that the chyle is absorbed from the intestine. (*See Essay, Syst. of Physiol. vol. 2, p. 363.*) For my own part, I believe, that if the modern doctrine of absorption can be sufficiently detailed and sustained, the general presence of the fibrils of the lymphatics of every part of the system, and the existence of the body with its vessels as cells of the living organism. Many physiologists have little difficulty in conceiving how fluids can be taken up by the lymphatics, but rather stagger at the notion of this being also the case with the nutrient fluids. Others, however, acknowledge their owed to both hypotheses, considering themselves to be then by the argument given. If the vessels capillary arteries can receive the dense, hard matter, the small lymphatics can receive it. One example is not more difficult to comprehend than the other. Yet, such reasoning leaves little light on the question, how are the some-purified for absorption, and in what manner are they taken up? These in fact remain completely unexplained.

"What inquiries a judicious physiologist are we to conceive of the intricate nature of this operation? If solution of the substance be necessary, we are at a loss to find a proper solvent; many of the solutions are insoluble in water, or in the serum that which is found in the vessels; while, on the other hand, it is perhaps not easy to conceive how the substances can be absorbed without being previously dissolved, and still more so, how the solids can have their texture broken down, and enter the vessels, particle by particle, as it were, and be suspended in the lymph in a state of extreme concentration? As I have already mentioned, these difficulties seem physiologists, including Bidder, endeavor to diminish by arguing that the lymphatics must be supposed to act only upon the elements of every texture, and that, on this principle, the absorption of solids is as easily intelligible as that of fluids, the same elements frequently contributing to the composition of both. However, it must be acknowledged, that all this kind of reasoning is entirely visionary.

It is conjectured, that while parts retain the vital principle, they are capable of resisting the action of the absorbents. According to Dr. Ross, dead matter is more easily acted upon by the absorbents than living, and in fact, "no part can be absorbed until its texture is dissolved, and consequently, until it is deprived of life. No substance can possibly enter the absorbents, while it retains its organization, so that it necessarily follows, that the preliminary step in the transport of the body is its decomposition." (*Essay, Syst. of Physiol. vol. 2, p. 363.*) He elsewhere explains, that by the death of a part preceding its absorption, is less required, "that it is no longer under the influence of arterial action. It therefore ceases to require the supply of matter which is essential to the support of all vital living parts, and the process of decomposition necessarily commences." To me a better account of the subject appears to be that which, describing of metaphysical and chemical reflections upon the supposed death and decomposition of parts, previous to their absorption, represents the absorbents as acting directly upon the individual atoms, particles, or elements of the various textures. We know nothing

about the vitality of these atoms, or elements, in their separate capacity; supposing them to possess it, we know nothing of the moment when they part with it, possibly, as their entrance into the absorbent system, such as we are completely ignorant both of the manner in which such elementary materials acquire the vital principle, and of the exact moment when they become thus endued.

What is applied to the lymphatic glands, their use is not precisely known, though various conjectures have been offered concerning it. As Dr. Ross observes, they may perform that they serve as important purposes, from the circumstance of every absorbent vessel, in some part of its course, passing through one or more of these glands, as was first observed by Haller.

Mr. Harvey is one subject, injected the lymphatic vessels from the groin to the neck, without filling any lymphatic gland, so as to prove a fact which, he says, is contradictory to the received opinion, that each vessel always pass through glands in their way to the blood-vessels. He tried, with regard to the abdomen, the absorbents not merely true, as he called the lymphatic vessels which every gland, there are others which escape them. He declares, that some of the lacteals in the mesentery do not pass into glands. (*Exp. Imp. vol. 2, p. 41, vol. 3, p. 14.*) On the other hand, Magendie, in his *Essai sur l'absorption*, does not mention the circumstance. (*Ess. Lymph. Hist. p. 3, vol. 4, p. 10.*) and Dr. Bantock refers us to Gendie's *Ann.* p. 14, in confirmation of the rarity of such an arrangement. (*Essay, Syst. of Physiol. vol. 2, p. 363.*)

The fact of every lymphatic vessel, constantly entering a gland is more part of its course, seems to Dr. Bantock to weaken the inference, that some important change is effected in the system, and through by means of the lymphatic glands. "But says he, the same mode of reasoning might lead us to conclude, that although the absorbent glands are necessary to the existence of the higher organs of animals, they are not, as far as the purpose of nutrition and growth possibly, as it appears that there are some classes of animals, which resemble the mammals in many of their sensitive functions, and in the vascular part of the absorbents, which are without any lymphatic glands, as are very sparingly furnished with them. It is not only in point but very contradictory that being positively to the mammals, which can assist us in explaining the necessity for these appendages to their lymphatic system." (*Vol. 1, p. 104.*)

Muller's theory that the lymphatic glands had a tubular covering, which entered them to act as organs of propelling the lymph from their cells into the veins externally, and thence towards the thoracic duct, so that they were, according to his notions, like so many little hearts distributed through the system. This hypothesis, which is contradicted by anatomy, requires no contradiction even observation in the living animal. If it were true, we should expect to find the duct larger, and not so large as to render even their entrance to the human absorbent glands a questionable point; were pulsating observed, with or strong, would be perceptible in the situation of every superficial gland; or, if the contractile uses of a gland, the gland would sometimes be enlarged, and sometimes considerably reduced. Yet none of these circumstances prevail. It is likewise to be remembered, that no jet of fluid takes place from the vein externally when they are cut, as they frequently are in surgical operations.

It is now to be taken into consideration that fishes are destitute of lymphatic glands (*see Anatomist's Comparative Anat. by Lawrence p. 616.*) yet the fluid in their lymphatic vessels must be provided to supply the use of the system. In the necessity of a vessel, no glands are observable; still, "in this animal, nature does her business as well, though the apparatus is differently constituted." (*Recherches Exp. Imp. vol. 2, p. 60.*)

It might be hypothesized in themselves, decidedly contrary; and whatever difficulty we may feel in agreeing with Bidder, that the absorbent vessels are destitute of several contractility, we can have no hesitation in adopting this conclusion with respect to the absorbent glands, considered as solid organs, without any reference to the nature of the properties of lymphatics within them.

The existence of a white thick fluid in the lymphatic

not larger (less a pin or two); but others are as large as an orange, and weigh four pounds.—See Minors's *Medical Atlas of the Human Gall, &c.*, and *Medical Chir. Digest*, vol. 4, p. 185. Morgagni saw one which appeared to him a misshapen finger, and Goussier, Guartier, Harnemann, Marcard, Oltz, de l'Acad. Royale de Chir. t. 7, p. 10, and others, have seen numerous of this nature, which were too bulky to pass out of the system without surgical aid. In certain examples, recorded by Harnemann and Harnisch, the passage of the concretion upwards towards the splenic and Hepatic veins of one concretion which was as large as an apple (*Epist.* 1. 2, tom. 2, Dig. 2, p. 237, and *Marcardi Anat.*, *decanat.* (*Schneider's* *Verh.* *Anatom.* t. 2, p. 127). Bland, Nesome, and Boyer give the particulars of some examples in which the concretions discharged very as large as a hen's egg. Mr. C. White extracted two from the rectum, which were nearly as big as the fist (*Ann. of Surgery*, p. 18); and in a boy, who died in an emaciated state, after continued pain in the abdomen, attended with frequent attacks of delirium, Mr. Hay found in the transverse vein of the colon so large a concretion that it could not pass any farther along the bowel, and appeared to have been the sole cause of the boy's death.—(*Practical Obs.* in *Surgery*, p. 598, ed. 2.) An analogous case is also reported by White (p. 28). It is stated in the *Ann. de l'Acad. de Chir.* that Dupuytren saw a concretion that had been discharged, which was two inches and a half in length, one inch and a half in diameter, three inches and a half in circumference, and the weight of which was three ounces and a half. But, judging by their weight, how much larger these must have been which were seen by Serapellus and Lettices, and which he describes; that reported by Dolans, which weighed two ounces; that recorded by Ormsby, which females weighing two ounces and a half; and is said to have been eight inches in circumference, and to have been taken out by force; that recorded by Schmidt-schmidt, which weighed four ounces; and lastly, the specimen, cited by Vissagius (*Litteratur. Med.* Dig. vol. 1, p. 151), the weight of which is alleged to have been half a pound.—See *Med. Wahn.* vol. 8, p. 125. It is observed by Hunter, that although examples of alvine concretions being discharged by vomiting are not so frequent as the foregoing cases, yet they are not infrequently met with. Many of these have been collected by Schlegel, and others are collected by Frey (*Pha. Trans.* No. 429). He attributes to the stomach, by Marshall, (*Quart. Journ. of Nat. Hist.*, par. 1, in *Vol. de l'Encyclop.* *Medica*, 1781), by Boissier, and by a long list of other writers, whose names and publications are specified by Ponsard.—(*Ed. Med. Dig.* art. *Calculus Vesicae*, &c.) With due care of observation, says Kuhn, may not be enlarged these concretions which are found upon dissection either in the intestines or stomach, whence probably in time they might have been expelled. Some of this description are recorded by Portal, Vey, d'Auvergne, Jaccard, &c. The cases related by White and Vey, in which the cases are completely abstracted, I have already mentioned; and to these may be added the instance quoted by Hunter, in which "Morgan found the jejunum entirely blocked up by a singular concretion.—See *Person. medic. varia* (p. 18) a *matra de calculis* calculeis, the concretion calculeis opacis, et rubis granulis, *Memor.* p. 5 and 6, 46. Vienna, 1825.

It is also observed that, with respect to the origin of alvine concretions, whether discharged from the alimentary canal upwards or downwards, some of them appear to be formed in that canal itself, while others pass out of it from other situations; and they all admit of being distinguished according to the place of their origin, and formation into three kinds: 1. hepatic, or biliary; 2. gastric, or intestinal; and 3. (what this author designates, as *matra de calculis* calculeis) alvine concretions, as the name implies, are derived from some part of the hepatic system; the portion, is intestinal, are formed within the alimentary canal; and the named concretions in the hepatic system, but afterwards get into the *caecum*, where they acquire an increased size.

On the subject of hepatic concretions, or biliary calculi, or gall-stones, as they are usually named, there is no point of the system where they do not sometimes appear.—*Epist.* Bland found them in the surface of the liver.—*Ed. med. Wahn.* vol. 8, p. 125.

A woman's very adhering to the protracted covering of her liver, and a woman's case is reported by Bouverie. Tait, Bouverie, Bouverie, and Bouverie have seen calculi within the substance of the liver; while Bouverie, Palfogian, Goussier, Bouverie, Bouverie, Bouverie, and Bouverie, several examples, in which the concretions were in the paracystic of the organ. Bouverie, Bouverie, Bouverie, Bouverie, and Bouverie have seen them in the biliary ducts, or probably were those which Goussier and Casanova may they found in the same cases. Whalley and Dietrich found calculi in the ducts hepaticus; Bouverie and Goussier in the ducts cysticus; and Bouverie, Goussier, and Bouverie, in the ducts cholelithicus. Goussier, Bouverie, Bouverie, Bouverie, and Bouverie have seen calculi in the ducts hepaticus, and Bouverie have seen calculi in the ducts cholelithicus, attached either to the liver or the gall-bladder. The place, however, where calculi are found in the greatest number, and with most frequency, is the cavity of the gall-bladder itself. Here they are sometimes single, their size varying up to a magnitude completely filling that cavity, as says Bouverie, Bouverie, Bouverie, Bouverie, and Bouverie have seen: while sometimes their number amounts to a hundred, or even a thousand, of different sizes. Bouverie possesses a gall-bladder, which contains above a hundred small calculi, and formerly I had a similar number, which I found in the body of a female. Van Swieten met with a hundred; Hunter, a hundred and forty; Stiller, two hundred; P. Tait, three hundred; Whalley, five hundred; Morgagni, seven hundred; Bouverie, a thousand; Hunter, seven hundred; Paul, sixteen hundred; Beck, two thousand; and Bouverie, several thousands.—*Bland.* *de Pathol. Anat.* t. 2, p. 401.

All hepatic concretions, however, are not calculated to pass from the place of their origin into the intestines, but only such as are situated in the ducts hepaticus, or its main branches, in the gall-bladder, the ducts cysticus, or the ducts cholelithicus. When their size is not disproportionate to the diameter of the ducts, they pass with facility; but, when their dimensions are larger than those ducts can naturally admit, the latter become stretched and dilated, whence arise the sharp pains and crises which attend the disorder, analogous to the sufferings produced by the descent of large stones from the kidneys to the bladder. The cavity of these dilatations of the hepatic ducts is generally disposed. Bouverie found the surface of the ducts cholelithicus, which is usually very small, so much enlarged that it could receive a finger; and Van Swieten saw this duct enlarged through its whole extent to a similar degree.—*Med.* in *Boissier's* *Epist.* de *Medic.* vol. 1, p. 150. Goussier, in describing a body, found the ducts cholelithicus so dilated, that it resembled a kind of bag, in which several calculi were included. Mr. Thomas saw alvine stones two cases, in which the point of the two finger readily passed from the cholelithicus into the gall-bladder.—*See Med. Chir. Trans.* vol. 8, p. 165. Bouverie saw this duct so much enlarged as to admit a couple of fingers, and he found many alvine concretions from Bouverie, Tait, Vey, and others. We may conceive how dilated this tube must have been in a case recorded by Richter, where, though it was not completely obstructed, a calculus weighing three ounces and a half was lodged within it.—*Bland.* *op. cit.* p. 7-15.

With regard to these concretions which are distinguished by the epithet gastric, or intestinal, some are formed in the cavity of the stomach; the rest in one or other of the intestines. They remain for a greater or less period in the place of their formation, according as they happen to be lighter or heavier, smoother or rougher, more or less adherent, or as the local general circumstances are more or less favourable to their retention or expulsion. Sometimes, they continue undisturbed until they have attained a very considerable size. In particular instances, instead of remaining constantly in any place, they successively pass through the whole intestinal tube, lodging at different points for a greater or less time. In the works of Hunter and Keen may be seen representations of the points of the intestinal canal, where these concretions have been found. The white substance, of which Morgagni has given an account, was some years in traversing all the convolutions of the bowels. These gastric or alvine concretions, which are very common in animals, are less frequent in the human subject, as is proved by the observations of Vossius

and Vaquaria, inserted in their valuable essay on this subject in the *Annuaire du Muséum National d'Histoire Naturelle de Paris*. In the latter they are accumulation of an inorganic kind, there may derive from an irritation not proved, in which has conception revealed *Barrois gemmæ*.—Voigt, *Monatsschrift für das Naturwissenschaftliche*, 6, 3, p. 575.]

As for the third species, which Rabinus named, and, as hepatic gemmæ, they have still been regarded in the hepatic organs, and assigned to the hepatic tubercles. Here, if the tubercles only be enlarged, and the contents of the vessels have a disposition to become thickened, and condensed round it, as a nucleus, it may be troubled larger by additional strata of matter, and would increase steadily, if a stop were not put to the accumulation by the narrowness of the canal, or in other mode. For the expansion of the concretion. Stages are also two instances of this sort of concretion; one from Glands, the other from Bile; and he gives his opinion that another alvine concretion, spoken of by Valet, must have been of the same nature. Dr. Cos. describes another interesting specimen, and others are referred to by Van der Meulen, Mucosa, Pott, &c. Perhaps, says Rabinus, the homogeneity of this kind would have been more transparent if all the concretions discharged from the bile had been mixed with greater uniformity, and the hepatic gemmæ distributions not associated with the hepatic. The judgment of these concretions in the intestinal canal is of singular duration, and depends upon a variety of circumstances. Van der Meulen gives the history of a calculus, which, as far as could be judged of by the path in the right hypochondrium, and the change of symptoms, must have passed into the duodenum in the month of January, and then continued in the bowels until August, when it was discharged from the rectum.

The crystalline appearance of alvine concretions is generally so conspicuous, that it has not escaped the attention of several of the old writers, as we may convince ourselves by referring to the Works of Gern, Gern, Girard, Berget, Berthollet, &c. It was noticed by Haller in his *Elementa Physicæ*, vol. 6, and by Morgagni in his *Epist. 31, de Solidis in Cæca, &c.* It says Rabinus, these crystallizations are not always plainly visible, and regular, but depends either upon their impurity, the heterogeneous nature of the accumulated matter, or perhaps on unfavorable circumstances, which would equally affect the process of crystallization out of the body.

Now, as all crystallizations depend upon the fluids in which they form, and from which they receive their crystallizing elements, it must be evident that, inasmuch as the fluids of the hepatic organs differ in their constituent principles from the fluids contained in the intestinal canal, the concretions produced in the first system must differ from those originating in the second; while the hepatic gemmæ itself will contain the nature and properties of both systems.

The first three which hepatic concretions are formed is unquestionably the bile, either some of its ingredients entering into their composition. Indeed, previously to the new chemical doctrine, hepatic calculi were generally considered as being simply condensed undigested bile.

From investigations made in more modern times, however, when the art of analysis has displayed a technique of which the old chemistry was not susceptible, it appears that although human biliary calculi yield the same products as the bile, there is contained in them more or less of a peculiar substance, which was named by the celebrated Pott, *alopoein*.—*Mém. de l'Acad. des Sciences*, 1769, p. 223. The presence of the substance in the constitution of such important bile, when it is situated in and in large proportion, the colored is regular and the crystallization well marked; and when it is in small quantity, the crystallization is confused and disordered, the crystals only exhibiting an irregular weakly concretion, more like a clot than true crystals. The kind of alopoein constituting the base of all human biliary calculi, had some resemblance to spermaceti. Both Fourcroy and Dr. Berthollet, who analyzed it, found it composed entirely of carbon, hydrogen, and oxygen. It melts, but requires a heat superior to that of boiling water, burns a flame like a seed, and has cooling power. Burns a substance, which besides was crystalline. It is not soluble in alcohol in the cold; but when the al-

cohol is heated on it, it is dissolved in a proportion according to Berthollet, of one part in sixpence—according to Dr. Berthollet, one in thirty.—*Nature's Journal*, 1801, vol. 4, p. 127. The substance, when it boils, deposits light whitish scales. It is soluble in ether in the cold, and more abundantly if the ether be heated. But as hepatic concretions dissolve in ether, and, according to them, it dissolves those which contain almost entirely of this peculiar matter; yet Dr. Berthollet has remarked, that oil of turpentine acts on it with difficulty, and even when digested with it, at a boiling heat, dissolves it only in a small degree. Pure oils and potash dissolve it completely, and reduce it to a saponaceous mass. As regards, as Dr. Berthollet has remarked, seems little soluble in vinegar when boiling. Nitric acid dissolves it, and, according to Fourcroy, converts it into a species of liquid similar to the oil of turpentine. This becomes concrete, but without any crystalline structure, and is more soluble in ether and the alkalis than the original matter.

The substance (Fourcroy has observed) is considered as greater or less generally in nearly all human biliary calculi, more or less impregnated with other matter, but still in its proportion as to these other bases. Hence, they partake of its properties; are fusible, inflammable, and more or less soluble in the agents which dissolve it.—See Murray's *System of Chemistry*, vol. 4, p. 594, ed. 5. Fourcroy, on exposing the three principal substances to the action of dryness, within the acid, saw it whitened; and afterward restore its former silver lustre. However, Rabinus repeated this experiment, and found that the whiteness which was contracted remained permanent.

While the hepatic system contains a fluid which is always partly of the same quality, viz. the bile, the accessory canal, as Rabinus observes, contains a less and different fluid, but is continually supplied by distillations of various nature, kinds, and properties, consisting of food, drink, and several secretions. All the principles which are so service for the formation and renewal of the different species of living solids, and of the many kinds of fluids, as first means more or less than in the alimentary canal, and these undergo peculiar changes. All the principles which, under different circumstances, may contribute to the production of natural concretions, either in the gall-bladder, the crista bladder, the kidneys, or in any other part of the body, where they ever occur, take at first into the intestinal canal, where they continue for some time. Such a multiplicity of principles, disposed to crystallize, and be converted into calculi, would very often, almost daily, produce these concretions in the bowels, were there not many circumstances which counteract this tendency. As, for instance, continue, the incessant motion of the matter itself, which the intestinal tube, the variety of these elements, whereby their reciprocal tendency to union is disturbed, and the decomposing and recombining influence of the gastric secretions, whereby parts are seized, disposed of, dissolved, and analogous matter kept divided, &c. But whenever these circumstances are not actively operating, as may be the case in a morbid, or old of the bowels, or in some preternatural case belonging to them; whenever the intestinal fluids undergo such an alteration that the production of these concretions cannot be prevented; or, lastly, whenever some favorable circumstance, such as an extraneous nucleus, forms a centre of evulsion for particulate elements; then the nature matter, which is most disposed to crystallize, and the earthy and mucous substances, &c., are attracted together, and produce more or less perfect crystallizations. A chemical analysis of some intestinal calculi, furnished by Koenig, and afterwards by Stern (Philosophical Transactions), proves that when they are exposed to a strong heat in distillation, they yield water, ammonia, and a thickened oil, a rigid membrane remaining behind. Under identifying a singular conversion, fluid, or solid, to the above products, phosphorus. The materials of concretions was afterwards discovered by Goubern, Fourcroy, and Vaquaria, in their analyses of the intestinal concretions met with in animals, describe them as composed of the anhydrous phosphorus of lime, phosphoric acid, and of the anhydrous phosphorus.

Some specimens contained in the Edinburgh museum were very carefully examined by Dr. Thomson: they at first soften in water, but afterward sink;

the specific gravity varying from 1.275 to 1.285. Distilled water, stirred from time to time with glass, and with glass, which separated in white flakes by boiling. These were also a peculiar brown substance, at first dissolving in water, but rendered nearly insoluble by more evaporation; soluble in alcohol, and most easily dissolving in vegetable extract. The specimens likewise contained minute of soda, crystallizing on spontaneous evaporation of the water; phosphate of lime, precipitated by ammonia; sulphate of soda in minute quantities; and, perhaps, sulphate of lime. Alcohol dissolved the peculiar brown matter and some of the soda; caustic potash, the albumen, brown matter, and perhaps some of the soda; and acetic acid a proportion of phosphate of lime. After all these remained a peculiar substance, having the color and outline of the calculus; in very short threads, soft, resembling silk, or rather wool, brittle, dissolving in water, alcohol, ether, petroleum, and nitric acid; being blackened, and partly dissolved by charcoal by sulphuric acid; slowly dissolving by heat, without effervescence, in dilute acid; and losing on evaporation a whitish residue, of longer taste, and imperfectly soluble in water; leaving with a bright flame; but dissolving on other animal and vegetable substances in some quantity, and disappearing from wool, by its insolubility in potash-ley. The calculus consisted of alternate layers, or concentric strata of this substance and phosphate of lime, in which the albumen and brown matter served as a cement, the other substances being in small proportions. Phosphate of lime mixed with a brown viscous matter, formed the external crust of some of the specimens. On the surface of a few were spotted crystals of phosphate of ammonia and sulphate. The presence of another porous, amorphous, carbonaceous of lime, urea acid, nor less could be detected.

Varieties have also been found by Dr. Harey and Mr. Berard, exclusively opposed by congress, of which the present has been in the habit of taking vast quantities.—See Thomson's Obs. in Medical Anatomy of the Human Urine, &c. p. 36, 37, in Medical Jurisprudence, vol. 1, p. 188, 189.

From observations made by Dr. Wallston, it appears probable, that the above thence light, though substance is derived from urine, which are so commonly taken as food in Scotland.

"If the calculus is directed in its length, as stone pebbles or beads, forming a small length, are seen placed at one of its ends. Dr. Wallston, observing these angles and comparing them with similar ones detached from the calculi, and forming the most solid in structure, situated behind, beyond all doubt, of their perfect solidity."—Marrat on Calculus Interstis, p. 124, 125, London, 1807.

The specimen analyzed by Dr. Ure, he ascribed to be a malformation of the bladder.—Hist. of Chemistry, art. Intestinal Concretions.

As the nature of hepatic-gastric calculi, they have further noticed a bilious character, regard which other substances contained in the bowels adhere; hence, it is evident, that as they are formed in the bowels, so they are two different, sometimes, and among various kinds, two distinct compositions must be the result. Although, says Rastor, there has hitherto been no scientific analysis of this species of calculus, respecting the very imperfect one by Merz, upon whose views, really wrong, that, if two separate analyses were made, one of the calculus, the other of the surrounding matter, there would be obtained from the waters the same results as those of the hepatic calculi, and from the rest those of an intestinal concretion.—See Ponsard's Essai sur l'Origine, &c. de l'Opacite des calculs de la vésicule de la bile, p. 25—27.

As the same subject remains, the foregoing principles will enable us to determine with greater precision than formerly, the characters which appertain to the several classes of calculi. It will be noted from the internal view; characters, by means of which these can be so differently in dividing, from the appearance of one of these concretions, the place of its origin, and its peculiar nature. The hepatic calculus being composed of bile, and also of albumen, its characters will be such as indicate the predominance of a bilious, sanguineous, and white fluid, and a well organized principle. The gastric or intestinal calculus, arising

from the masses of viscous mucus, curdles, and other principles, which happen to be at the alimentary canal, will have very different characters, generally indicating its gastric, or intestinal composition. Lastly, the hepatic-gastric calculi will present a union of the different characters, viz. in the common, the characters of the hepatic calculus, more especially, than of the gastric.

The criteria for distinguishing the several kinds of calculi from each other may be divided into such as may be termed external, being derived from accidental circumstances attending the foreign body; and others, which may be called internal, being derived from the internal characters belonging to the composition and nature of these concretions.

The first of these external criteria is the age of the patient. C. Scapellato, Hoffmann, Bouchard, and Morgagni of ages, their history, external signs, except in subjects of advanced age, and never in youth. And Haller writes, "Quatuor et prope, quantum cum, in aetate adulescentia." Morgagni met with only one old person who had alvine concretions, but without eight young persons, not one of whom was above the youngest being twelve years of age, and the oldest twenty-nine. To these I may add the instance reported by Boyl, in which a stone as large as a hen's egg was found in the gall-bladder of a young female aged only twelve.—See Journ. des Savans, Sept. 1807. The cause of this difference is attributed to be explained by Morgagni; but, perfectly, a more rational explanation than that supposed by him, will be found in the analysis of the title of old and young subjects, we made by Ponsard and other modern chemists. From these and other observations, offered by Rastor, it is rational to conclude, that when an alvine concretion is discharged from a young subject, the organs are, that it is not a bilious one; though, if the patient be of advanced age, it is not to be inferred, that the bilious nature expelled must certainly be bilious, because gastric or intestinal concretions are common in individuals of every age.—Rastor, op. cit. p. 13. Indeed, with the latter kind of calculi, men of advanced age and women are said to be most frequently affected; children and young persons rarely suffering, unless the formation of such bodies has been produced by the presence of flatulency, or other indigestible substances, which serve as nuclei.—Rastor, Nouveau Cours, t. 2, p. 125, ed. 1. These concretions are also sometimes formed in patients who have been confined by disease a long while in a protracted posture.

The second criterion is derived from the symptoms, which precede or accompany the expulsion of the calculus. Sense of heaviness, irritation, and pain in the region of the liver, pain along the mamma cartilage and navel, bilious swelling, jaundice, and other symptoms of the bowels or constipation, are the symptoms which, especially when they frequently occur, indicate the hepatic origin of the calculus, and proceed thus ascending through the narrow ducts of the liver calculi towards the intestines. The most careful observations takes place, however, that these symptoms are only to be depended upon when taken collectively, and that no single one gives any certain information. Also, if their presence be sufficient to prove the hepatic origin of the calculus, their absence can by no means be regarded as a proof of the concretion being of the intestinal kind.—Rastor, p. 13.

Third criterion. A calculus voided may be set down as undoubtedly hepatic, if accompanied by intense jaundice of the nature. It is also recorded by Harey, and in another by Vater, the absence of common symptoms in the first, and the magnitude of the calculus in the second, united decide whether the concretion were not more likely to be of the intestinal kind, than of the hepatic. At length, the bodies having been opened, the presence of other similar calculi in the gall-bladder afforded an adequate criterion.

Morgagni has done a fourth criterion, deduced from the number of the calculi voided; which, if very numerous, are to be considered as bilious. Balthus writes, however, the fallacy of this test; both hepatic and gastric concretions being sometimes single, sometimes in various numbers, from up to a thousand, and he refers to a case where a very large number of concretions of the gastric description were voided, as reported by Kozig. The test here suggested, therefore, may be considered as generally valid; for, the number of in-

testinal concretions is rarely more than two, though sometimes very considerable.—(T. Thomson. See Med. Chir. Journ. vol. 4, p. 180.)

I shall now follow Botta, and name three characters of alvine concretions, which he calls internal, and are deduced from their quality and composition, beginning with the criterion furnished by the use of the extraneous substance voided. As the bilious facts are rare, it is obvious, that if the calculus be above a certain size, it cannot have passed in that state undissolved through those narrow tubes, and consequently must be either of the gastric description or fecal, having passed the hepatic system whole, and, after being increased within the alimentary canal. The question, as Botta means, this criterion has no considerable weight, especially when the discharge of the calculus has not been preceded by pain, or other symptoms indicating such violent obstruction, as the above facts must have suffered from the passage of the foreign body. These are certainly evidence of being diluted in a transitory degree, as some facts already noticed in this article, sufficiently prove; but such dilution can only happen, without pain, irritation, and a serious pain of sympathetic efforts. Botta remarks, this criterion will only apply to large, and not to dissiminate concretions. A bilious calculus, as previously said, was found by Mr. Rogers, of Barbours, to have passed by absorption directly from the cavity of the gall-bladder into that of the duodenum, whence it was voided from the anus.—(See Med. Hist. Trans. vol. 14.)

A second criterion is the colour of the calculus; a test advised by Mead, who asserts, that bilious calculi are yellow or green, and intestinal ones grayish brown or black. But, says Botta, one need only look at various specimens of alvine concretions, and read the statements of authors who have given great many of them, particularly Morgagni and Boerhaave, to comprehend, that this criterion deduced from their colour is most fallacious, every species of them presenting great variety in this particular. And it is to be remembered, that the bile and the intestinal fluids, whence these concretions are formed, differ in colour in different individuals, according to a variety of circumstances, in health and disease. And species of hepatic calculi has a white colour, but is sometimes yellow or greenish. Alveoli is of a round or poly. round shape, and often of a gray colour externally, and brown within. A third is of a deep brown or green colour.—(See Doct. Dict. of Chemistry, art. Gall-stones.) The small intestinal concretions, examined by Dr. T. Thomson, describe a coating, resembling lead yellow colour; the larger were varnished with an earthy matter, or a yellow colour, and purple or sometimes white.—(See Memoirs on the Human Gall, &c., and Med. Chir. Journ. vol. 4, p. 185.)

Third criterion. The progress or absence of a reaction will enable one to judge whether a calculus be gastric or hepatic. A bilious concretion can no longer, properly so called, that is to say, it has no foreign body in its centre. When a transitory matter is made of such a calculus, one finds either a cavity in the middle, or the getting by which this part of its substance can be distinguished from the rest; or if a reaction different from the other part of the concretion is apparent there, it contains pieces of bile, either greenish, differently coloured, or more or less fluid than the rest of the calculus, but which is nevertheless invariably true. On the contrary, every gastric concretion has, still were, an extraneous matter, as Flucrocy and Vissaghi have explained in their own way the intestinal calculi, then within its middle. Botta, in the Med. Trans. gives an account of some alvine concretions which were found round pieces of wood. Botta himself, in example of a crystallized calcareous foreign body, a broken bullet. Had he not with a calculus in the course of which was so firm and. Extraneous bodies upon fruit-stones are recorded by Clarke, White, and Hey, and also in the Ephem. Med. Histor. And some in which the nucleus was a small portion of bone, and Vissaghi, Flucrocy, and others describe alvine concretions formed round calcareous extraneous matters, and many similar cases are specified by Vallisium, Van Meenen, and others. In the hepatic-gastric calculus the bilious concretion seems at a nucleus for the gastric. According to Dr. T. Thomson, the nucleus is commonly a cherry-stone,

a small piece of bone, or a bilious calculus.—(See Med. Chir. Journ. vol. 4, p. 185.)

A fourth criterion is deduced from a certain similarity which belongs to bilious calculi, but not to those of the gastric class. This similarity is more palpable when the calculus has been recently voided, or when it is loaded with warm faeces. The similarity is still more evident when the concretion is cut or broken, as then the knots, saw, or fingers become smeared with superfluous particles, which adhere to them. In order to dissolve an hepatic calculus, however, the necessary heat, perspiration, and substances, and not merely a four tenths its volume, for a gastric, vesicular, or other concretion may by accident become coated, as it passes through the bowels, with a stratum of bile or superfluous matter. When the similarity is detected externally, or in the examination of a calculus, but is found in the interior, it is a clear indication of the hepatic-gastric formation of the concretion.

Fifth criterion. The specific gravity of a calculus, the property which it has of floating or sinking in water, has been long considered as a test of its species. The hepatic calculus is generally specifically lighter than water, as most city substances are; on the contrary, gastric calculi are specifically heavier than water, like all varying matter, and of course sink in that fluid. This criterion was often employed by Boerhaave, Ferrius, and others, for distinguishing various concretions. But it is of no more use, as many bilious calculi weigh only a little more than their bulk. The specific gravity of that analyzed by Dr. Ford of Glasgow, was 1.010.—(See Med. Chir. Journ. vol. 4, p. 172.) As Botta observes, this test will not answer for hepatic-gastric calculi, which are subject to great anomalies.—(Ponsen, Art. p. 21.) Nevertheless the most correct modern investigations prove, that gastric concretions have a specific gravity varying from 1.376 to 1.541.—(Dr. T. Thomson in Mead's Med. Ann. &c., and consequently their general character is to be heavier than bilious calculi.)

A sixth criterion is that proposed by Vign d'Ange, in the Mémoires de l'Académie de Médecine, and deduced from the figure of the crystallization. According to this writer, intestinal concretions crystallize in concentric layers, shaped like a rock's creek, when the crystallization of bilious calculi is indicated and well-developed. Although this criterion is necessarily founded upon the known laws by which every crystallized substance acquires a peculiar and determinate shape, yet it may be generally observed with respect to the mark of distinction here proposed, that the concretions of which we are now speaking are usually too irregular, and too much disturbed in their crystallization to exhibit a regularity, for which simplicity and gradual are indispensable. Hence many of these concretions do not present the slightest vestige of crystallization, while others scarcely show a trace of it, in the shape of a large quadruple mass. The white-colored hepatic calculus when broken is said to present crystalline plates within, brilliant and white lustrous. The round or polygonal one which is often of a gray colour externally, and brown within, is described as consisting of concentric layers of compressed bile, usually with a nucleus of the whole crystalline matter in the centre. Lastly, the hepatic calculi, of a deep brown or green colour, when broken, are said to exhibit a number of crystalline the calcareous crystalline fragments, filled with impregnated bile.—(See Vign d'Ange, art. Gall-stones.) With respect to the special shape assigned by Vign d'Ange to the two classes of alvine concretions, it may be observed that the specimens we speak of from animals, and that consequently the inferences made from them are not applicable to calculation of an analogous nature discharged from the human body, because, as the bile varies in different animals, so must the fermentive principles of the calcareous crystallizations. It is further remarked by Botta that the calcareous termed alveoli, which is the basis of bilious concretions, was not found by Needham in hepatic calculi taken from birds' nests.

A seventh criterion is founded upon the inflammability of an alvine calculus. A bilious concretion being necessarily made up of compounds of fat, resinous matter, together with sulphur, or heat, and other acids, and other. When this compound is made in close vessels, the products are hydrogen, carbonic acid gas, oil, and ammonia; some caloric and much remaining

restoring the active secretions from the nervous energy as long as his life. When the system has well and flows the contractions as he takes out, the muscle would be divided at its posterior angle. According to Richerand, such a division does not permanently weaken the fibres to a perceptible degree, and the paralysis seems to originate from this cause.—(Nouveau, *Chir.* t. 3, p. 428, etc.; 4.) Macleod, affirms proper division, with excision, extracted from the nerve an above circumference which weighed four ounces and a half, and was of an oval form, the granular character being two inches eight lines, and its surface was such seven lines.—*Nov. AMAUROUSIS, (Passio) *impedire* to darken or obscure. Oculi strabismus. Oculi strabismus. (Et. L'Amateur.) Bern. Schönerer Star. According to Boer, the term amaurosis properly means that darkness or total loss of sight which immediately depends upon a morbid state of the retina and optic nerve, whether this actual state exist as the only defect, or be combined with other defects, whether it be a primary affection, or a secondary one induced by previous disease of other parts of the eye. He may say, with a typical variety, that the term amaurosis designates all affections of the nervous vision, which produce either complete or partial loss of sight, whether this arise from strabismus or other organic disease, from a luxation or loss of sensibility in the eye, which direct be traced to change of structure or any other evident cause.—*Nov. Journ. de Med. et Chirurg.* vol. 4, p. 166.

The definition given by Mr. Lawrence in his *Lectures* appears to be correct and comprehensive. Amaurosis and pama strabismus, he remarks, are names applied indistinctly to those forms of strabismus which result from

an affection of the nervous sensitive of the eye, whether it be seated in the retina, optic nerve, or elsewhere; or whether this affection be produced immediately by vascular congestion, inflammation, or venous clump; or indirectly by sympathy with other organs.

Even these definitions, which comprehend every form of amaurosis, it is evident that this disease does not uniformly take place as a single independent disorder, but often subsequently presents itself as a symptomatic effect of some other disease of the eye, a fact exemplified in cases of hydrophthalmia, sympathizing ophthalmia, &c. Also, as Mr. Wardrop observes, amaurosis, in its usual conception signifies a symptom of disease as well as a distinct affection.—*Lectures by the Medical Anatomy of the Human Eye*, vol. 2, p. 164, 165, Lond. 1808. With respect to the mere loss of the light of vision here implied by amaurosis, the correction will remove the error, whether the loss be total or partial; whether the eye be permanently blinded or obstructed; and whether it be perfectly clear and transparent, or more or less turbid; for the name only refers to the morbid state of the retina and optic nerve, and not to the condition of the light in passing. When the long-embodied name of amaurosis is removed with this precise meaning, there will not be the slightest danger of confounding the disease with other affections of the eye. However, when it is wished to indicate the very different forms and kinds of amaurosis, the foregoing appellation of the title and page are considerations of great importance.—*See Boer's Lettre von den Augenkrankheiten*, h. 2, p. 423, 424. Wern. 1817.

I think it also of importance that surgeons should well understand what Mr. Travers has particularly mentioned, that the term "amaurosis" comprehends all those imperfections of vision which depend upon a morbid condition, whether affecting structure or function of the nervous apparatus proper to the organ.—*See his Synopsis of the Diseases of the Eye*, p. 308.

Boer mentions four species of strabismus.

The first is a genuine, unaccompanied strabismus, the characteristic symptom of which consists peculiarly and entirely in an impairment or loss of vision, without any marked change in the organic matter of the eye. This is also the epithet "proper Amaurosis," used by Mr. Travers, would be applicable.

Secondly, there is an amaurosis, which, besides being attended with a distortion or total loss of vision, is also accompanied with appearance of disease in the organic matter of the eye.

Thirdly, there is another strabismus, in which, together with the above principal symptoms, viz. weakness or loss of sight, there are also marked phenomena exhibited in the form of the eye in general, or in particular structures, and especially in the action of its intrinsic parts.

Lastly, Boer says, he will often point out an amaurosis in which all the characteristic symptoms of the three preceding cases are more or less combined.—*See Lettre von den Augenkr.* h. 2, p. 476.

The genuine unaccompanied amaurosis, consisting of a mere impairment or loss of sight, without the appearance of any other defect, is one of the most intractable forms of amaurosis, not only because nearly all attempts to cure fail, but because they can rarely operate directly upon the optic nerve.

In the true unaccompanied strabismus, namely the simple quality of the optic nerve and retina are affected, and after doing nothing permanent can be traced in those parts either within or on the outside of the eyeball. It is, in short, the case in which the function of the retina has become imperfect or destroyed, the eye appearing in other respects sound.

According to Boer, this simple unaccompanied form of amaurosis is subdivided into that anatomic weakness of sight or blindness, which depends upon the inability or failure sensibility of the optic nerve and retina being too highly excited, and into another case, the progressive cause of which is perfectly sick entirely conformable to depression of such vitality or sensibility. The first instance is much less common than the second.

Amaurosis does not constantly attack both eyes at the same time, frequently one is attacked some time after the other, and it is not unusual, even for one eye to remain sound during life, while the other is completely blind. This depends, in part, upon the disease

tion to the disease in one eye being quite local, and is just upon the reason given true to the consistent en-
tailing their operation only to the eye affected. Where
also the origin of anastomosing vessels is dependent although
upon constitutional causes, one eye is not infrequently
affected much sooner than the other; though in these
examples, it is more rare to find the eye which does not
suffer at first continue perfectly unaffected. (Went 3,
p. 334.) As a general observation, Mr. Wadding
thinks it may be remarked, that when only one eye be-
comes affected, anastomosing from a sympathetic affection,
there is little danger of the other eye becoming blind;
but that when keratitis is produced by any organic
change in one eye, the other is very liable to be symp-
tomatically affected.—(Course on the Medical Anatomy
of the Human Eye, vol. 2, p. 180.) Anastomosing very not
completely hinder vision, a diminished power of seeing
often remaining during life. Hence the division of
nerves too perfect and unperforated; which latter, how-
ever, sometimes admit a degree in which the patient is
only just able to distinguish light, the direction of its
rays, and shadows.

Imperfect animals, besides being characterized by a considerable weakness of sight, approaching to real blindness (*Apocrypha Astruciana*), is mostly complicated with a *proptus* or loss of power of other mental associations, which merit serious attention.

Among the most important of these synoptic signs are the appearance of important landmarks in a collective or territorial sense (*visus territorialis*). For instance, when the patient is reading, single or double words, or lines cannot be seen, unless the eye be first directed to them by a movement of the whole head, and greater or less portions of other objects are, in the same manner, indistinguishable. Sometimes, stereoscopic pictures can see only the upper or lower, or the left or the right half of objects (*visus dissidialis*): *Ammonius* (*Ammonius*: *Hemipus*: *Hemipus*).

Sometimes, when the patient attacks one eye, he can only distinguish the halves of objects; that is, he opens both eyes, he sees every thing in the external form. In this case, according to Schaeffer, one eye is normal and only some fibres of the nerve of sight may be injured in the other. — (Vergessenheit Chir. Schmid, 6. 2. p. 12.)

There are likewise some not very dissimilar cases of imperfect anisometropia, in which the patient cannot see an object, unless it be held in a particular direction before the eye; but when the eye of head is turned in the lens, he loses all view of the thing, and cannot easily get light of a scene. — (Jews, *Letter from Aug. 1840*, p. 15, p. 154.) On this part of the subject, it is remarked by Brider, that persons who may be said to be entirely blind, sometimes have a small part of the retina which is still susceptible of the impression of light, and is usually situated towards one side of the eye. This elasticity of sight sometimes gets pointed out by the late Mr. Hry, as common in the present disease. — See *Med. Obs. and Inquiries*, vol. 3. Brider mentions, that in one man, who was, in other respects, entirely devoid of vision, that sensible part of the retina was situated of largely over the nose, and so small, that it was always a considerable time before an object could be discovered; he adds, that it was so movable, as not only to discover the light, but even the spot of a distant object. According to this author, it is the centre of the eye that seems to be the first and most seriously affected. Hence, the mortality of persons, who have a beginning of imperfect anisometropia, are persons, which are naturally blind, before they reach an age immediately before death. — (Anfang, p. 15, p. 154.)

[illegible]

The relative perception of various calibrations left is rapid motion before the eye, gradually increases; the

solitaneous Cataglyphis become less and less transparent, and, at length, the so connected together, they form a kind of network or paste, by which all insects are more or less obstructed. This is another symptom of antismine, technically called *verru* vulgaribus. The network commonly has the peculiarity of being black in very light situations, or when white substances are before the eye; while, in dark places, it is rather shining, red, or it seems, of a bluish white line like silver, though sometimes of a milky-yellow *glaire* colour.

A not transcribed synonym of jaggeded maddness is the palatine maddness every object indistinctly in a rainbow-like, wondrously iridescent, and generally very dancing light; while, in the dark especially, blue or yellow dusts, or very little seem suddenly to pass before the eyes when the eyelids are shut, and excite considerable alarm. (Vesta localis). Marrowygi (Heterotaxia, Pteridaria.)

In important anatomists, the acuteness of the retina may be so exaggerated that the patient shies at all very light places, particularly those in which the light is strongly reflected like the eye, and, in order just to discern in some transition large objects, he feels himself obliged always to seek shady, darkened surroundings, or to screen his eyes, not of course with a given object, or given glaucoma. This state is termed by Meier, Lichtscheu (Photophobia). Under these circumstances, it sometimes happens, that the patient for a very short time, he changes a few moments, what is very unfortunate for a more considerable period, is able of himself to discern the smallest objects in a weak light, more plainly and accurately than the best eye can hardly do in a good light. Yet, accepting at such position, the patient with the above degree of light is not capable of seeing even larger objects. This intimate of night requires the same of eyes.

Sozialismus; in the early stage of socialism, all objects seem endowed with a dense mist; while, on other instances, this mist first presents itself as a simple, essentially increasing socialism, and rarely in the form of a non-work or game; but in the present, when his blindness coincides with the same blindness, the mist finally appears for a day or two of a light gray color, and then the another day or two very black, every thing appearing as if looked at through a dense gray smoke. — *Beitr. Lehre von den Angewandten Mathem.*, S. 2, p. 499–500.

To the eye affected with imperfect vision, all objects frequently appear indistinct, but double. (Vision duplicata; *Diplopia*.) It is remarked by Schrevelius, that in the gatta strata, which seems to gradually acquire sometimes sensibility, with both eyes. He once cured a tiger of blindness, who saw the three sides of his quadruped cage; and he attended another gentleman similarly afflicted. Such cases, he observes, are brought on by a violent distention of the vessels of the choroides, where, he thinks, vision may easily arise, in consequence of the weak resistance of the tunics. In this manner, the filaments of the retina suffer pressure, and the rays of light are broken. Under these circumstances, if foreign assistance be not afforded, total and frequently incurable blindness may be the consequence. — Schrevelius met with an remarkable instance of this kind, in a young man, thirty-one years of age. When the patient made application for advice he had been blind a year. Before he lost his sight, he remarked, that after any violent emotion, his sight at first grew weak, and that objects appeared doubled or double. When no emotion was at all heeded, he saw black spots before his eyes, and at length was quite blind. The vessels of the choroid were so large as if they had been injected with wax, and every kind of surgical assistance proved ineffectual. — Vermeulen Citat. Schrevelius, p. 2, 3, 12, &c. Nov. Berol. 1768. It seems now, according to Borel, double vision only occurs when the patient looks at objects with both eyes, and it comes in some instances either the doubled or the natural eye. In the last of these circumstances, double vision only originates from the deviation of the axis of eye from the axis of sight, that is the first instance; it comes from the morbid state of the retina, next or the doubled eye. For the purpose of distinguishing both these varieties of *diplopia* from every other species of *opacitas* double vision, Borel applies to them the name of *diplopia verus*. A degree of *opacitas* (strabismus), there-

See, is a very common symptom of incipient amaurosis, particularly when only one eye is affected, for the optic nerve more or less loses the use of vision. It is owing to this loss of perception, that persons affected with an incipient amaurosis of one eye often mistake the relative distance of objects, and frequently see them reflected. (Trauer's Synopsis, p. 110.) It is less usual for the incipient amaurosis to be accompanied with what Boerhaave objects of the eye (Lacustula), which is papillary, or a convulsive, irregular action of one or more of the muscles of the eye, being evidently a reaction of the susceptible apparatus. (See Boer's *De oculo* Amsterdam, 1722, p. 87.)

They have often met with patients labouring under incipient amaurosis, who could plainly distinguish all objects which were not very small, but saw them of a different colour from their real one. For instance, red, yellow, green, purple, &c. (Vires coloratas; cupreus.) He had under his care an ancient woman, who at midday could discern even the smallest objects in a strong light; but they all appeared yellow, though no mark of jaundice could be perceived.

Amaurosis, in the early stage of strabismus, all objects appear quite distorted, bent, slanted, and, in some instances, inverted (Vires delictas; Melopsychia). Thus the face of a candle appears very long, but all every. (This is said by Boer to be constantly an antecedent sign, at the close of it lies in the brain itself.)

Incipient amaurosis is sometimes attended with considerable short-sightedness (Myopia); and sometimes with the opposite defect (Presbyopia); an infallible proof that essential changes have happened either in the transparent media or in the trunks of the eye.

Many patients, when first attacked with amaurosis, every where testify a great anxiety to have a great quantity of light, employing several candles at night, and sitting in the day-time with their backs against a window, in order to let whatever they are reading have a very strong light upon it. This excessive disposition of incipient amaurosis is induced by Boer, Lacustula.

Amaurosis may either take place in an instant, even so as to be attended with entire blindness; or it may come on gradually, that is, it may be complete in a few days of vision; or lastly, what is most frequently the case, it may be produced gradually, and several passages before it attains its utmost degree; consciousness of great moment in the diagnosis and treatment.

The type which the German authors in its course and development, is also subject to great variety, and claims the various attention; the amaurosis may either be permanent or temporary. It is sometimes an intermittent disorder, making its appearance at regular or irregular intervals. In certain examples it proceeds at particular times, scarcely all day, till a certain hour; or from one day till the next; or it is stated but every month. The attack sometimes takes place at intermediate periods. In particular cases, whether mental affection is associated with the impairment of sight. Boerhaave tells us that one became blind at twelve o'clock in the day, when the other eye, used to bear down pain. The attack always lasted twenty-four hours. On the following day at twelve o'clock, the sight went in return, and the patient then suddenly resumed the power of seeing the other eye. He would continue thus able to see for the next twenty-four hours. Whenever he took back, the disease was rapidly doubled; that is to say, the eyes then alternately remained blind forty-eight hours, and returned the power of seeing for only twenty-four. In another patient, cited by the same writer, the symptoms, during the blindness, always became disordered, weak, and turbid; but the transparency was retained in the condition of the vitreous. According to Boerhaave, the periodical amaurosis commonly depends upon immoderate affecting the digestive organs, the stomach of worms, or irregularity in the menstrual discharge. Sometimes it is plainly a symptom of a confirmed scurvy, the patient being attacked with an ordinary intermission, and blind during each paroxysm, but always regaining his sight as soon as such fit is over. (See Boer's *de Myopia*, p. 12, cap. 11.) Boerhaave tells that periodical amaurosis is rarely, if ever, in children, hereditary, hysterical, and hyperchaudral subjects. Dry-Sightless Albinus Boerhaave.

Nystagmus and night-blindness (Cecitas Corporalis) & Strabismus (eye looking more than once of the medical symptoms. But sometimes the frequency occurring first in the disease continues itself to be permanent type; and on account of its irregularity, it is then termed by Boer "amaurosis vaga," which, he says, is often of spasmodic origin, and therefore principally met with in persons liable to hysteria, hypochondria, convulsions, or epilepsy. Periodical amaurosis, when remaining, retained a certain time, often becomes permanent. (See Boer's *de Myopia*, p. 12, cap. 11.)

In amaurosis in general, but particularly when no material knowledge can be acquired of causes, and the treatment must of necessity be restricted to respiratory principles, it is of the highest importance to neglect what Boerhaave has pointed out; namely, the systematic exercises, and universal gymnastics, breathing, as a means of sensibility in the eye, is some attention affecting this organ. In moderately light places, the patient can distinguish things very well; but in a great light, he is not able to see at all. The eye is sometimes so affected, that a strong light will make it weep and become painful. Patients of this description often strive to wear a shade, however bad their sight may be.

This form of amaurosis is described by Boer as having two stages; in the first, the patient never loses sight; the symptoms not being lost till the end of the second stage. The disease always forms with great quickness, so that the limits between the two stages are frequently very indistinct.

The first stage commences with a peculiar sensation of fulness in the eyeball, joined with occasionally increasing, violent, and annoying, lachrymation, and a remarkable weakness of sight. These symptoms are soon followed by a striking, constantly increasing blindness, during which the power of vision gradually diminishes, without the slightest action being perceptible either in the eye itself or its surrounding parts. The patient, however, is always much to be afflicted consistently, on, at all events, by such symptoms of general and local plethora, and of a plethoric diathesis, as cannot be mistaken.

When the fulness of the diathesis into its second stage the weakness becomes irregular, being less violent in some vessels than others; the patient feels as if there were before his eyes a thick net or gauze, which, in a bright light, appears quite black, but in the shade, dark and shining. This net or gauze, when there is any temporary diminution of blood to the head and eyes, as, in straining at stool, is immediately rendered considerably more dense; and when such concentration of blood is often repeated, or long maintained, the density at length remains much greater than before, and, consequently, the patient suddenly grows more blind, and is very quickly entirely bereft of vision. This complete loss of sight, in the second stage, if efficient assistance be not given, is ultimately produced by the progress of the disease, even without any accidental determination of blood, though never quite suddenly. At last, all power of discerning the light is destroyed under incessant stayings lachrymation, which are sometimes weaker, sometimes stronger, and attended with a sensation, as if the dimensions of the eye were increased, and, indeed, it really feels larger than in the healthy state.

Sometimes amaurosis originates with symptoms of weakness and diminished insensibility. The sight is cloudy, and the patient finds that he can see better in a light than in a dark situation. He feels as if when he is at that time upon his eyes, and is in the habit of frequently wiping them. The power of vision is greater after meals than at the time of fasting. The sight is always clearer for a short time, after his natural power of vision ceases, such as hardness, redness, &c. Boerhaave refers to a person, who was nearly quite blind, but was constantly able to see very well for the space of an hour, after drinking champagne wine. He was retaining a, somewhat entirely bereft of sight, who was in the habit of having it restored again, he laid at home, whenever she without a quick pace, up and down her garden. The disease sometimes is seen in the case of a lady, who had been blind for years, but experienced a short recovery of her sight, on having a tooth extracted. (See Boer's *de Myopia*, p. 12, cap. 11.)

Whether the benefit arose from the stimulus of the operation, or Boerhaave is in error, or from the

reversal of an irritating cause, does not usually be complicated. A similar case is recorded by Mr. Travers, who says, that he has seen an idiopathic functional anisotropia distinctly attended by the contraction of a diseased limb, with the injury of a similar opposite and occasional slight scars on the opposite side two years before. — (*Opuscula*, p. 236.)

When the disorder is accompanied with diminished sensibility to the eye is general, Ross (see Richter, with respect to the temporary impairment of the sight after a surprising event, or striking emotional impetus; or when the patient's mind is excited with joy, or anger, though with impairment of sight, it is rare, is but of very rare formation. — see also Verch's *Traité des Affections de l'oeil*, p. 17.)

On the other hand, it may be remarked that every thing which tends to depress the passions and spirits, augments the imperfection of sight. Where signs of lowered sensibility prevail, the above-mentioned circumstances converge a transient functional impairment; the patient strongly relies from every strong light, and frequently shades his eye with his hand, &c. — (*Lectures des Anstretes*, b. 2, p. 524.)

Mr. Travers also knows patients, whose vision is benefited by a dark degree, and states, in which it is much diminished, by the continued circulation of a salt meal, and a few glasses of wine. The disorder is acute, and persons of spare and delicate habits; the latter generally. — (*Synopsis of the Diseases of the eye*, p. 157.)

According to Rost, this anisotropia differs from the preceding, by its functional being usually very slow, and its not exhibiting any traces of those two very different stages which are peculiar to the other case. It also invariably commences with the vision retinitis, or melanosis, without any allusion with a fluctuating play of light; and the eye is at sometimes considerably better, and sometimes weaker, which always depends upon the accidental operation of the above-mentioned or several circumstances. The manifestation of the eye is never continued long, while the duration of it is not only variable, but extremely and variable. It is not at all uncommon for this species of anisotropia to make its appearance at a night-blindness, because constant artificial light is again exposed to make the impression upon the diminished sensibility of the optic nerve, and consequently these patients always show a partiality to a very strong light. To such weak-sighted individuals, the flame of a candle, or the sun, appears as if covered by a dense veil, with an extended halo round it of various colours. There is no complaint made of pain in the head or eyes; and no sensation of fulness or weight is experienced in the eyelids; such low and there any signs of the disease in the structure and form of the eye, or in the action of its irritative texture; but when a low lens long continues, it is usually corrected with a designated habit.

Anisotropia either presents itself as a positive unaccompanied affection, or, at least, with the appearance of such a form of disease of the eye, depending solely upon a morbid state of the optic nerve, and compatible by a distention, or complete abolition, of the power of vision; or the disease is connected with other diseased appearances, either in the eye, or vicinity, or some other organ at a distance from the eye, or in the general constitution. When appearance with the most violent consideration, because they are the most just connected with the cause of anisotropia. According to the statement then, there is a positive local anisotropia, and a complicated anisotropia, which last may be either local or general, or of both descriptions together, and therefore named by Rost, "perfectly complicated." — (*Vol. vi.* p. 33.)

The general system of the strictly theoretical aspect of anisotropia, getting out of consideration the morbid increase, or distention of the sensibility of the optic nerve, are then described by Rost. In the first place, all morbid appearances are absent, which might be produced in the anisotropic eye by any one unaccompanied change in the texture, form, or state of that organ. Hence we are obliged to treat strictly exclusively the pathological anisotropia that has sight is bad, or quite slow, and can unaccompanied of recovery, especially in partial cases, is every position artificial in order to determine whether such anisotropia be true, particularly when the patient alleges that the blindness is restricted to one eye. Secondly, when the anisotropia is induced solely or quite formed in one eye, a

slight degree of anisotropia is or more perceptible, arising from the immobility of the patient's eye during the eye affected upon any object. Third degree of anisotropia is noticed by Adelman and Fischer as the worst sign of anisotropia. — (*See Klinische Anstretes von Jena*, a. 1, p. 141.) And it is particularly pointed out by Richter as an inevitable attendant upon anisotropia. The patient, says he not only does not turn either eye towards any object, in such a manner, that the object looked at is in the axis of vision, but he does not turn both his eyes towards the same thing. This was pointed by Richter as the only symptom which we should trust, where imperfect anisotropia should not be put in the more assurance of the patient that he is not well, while all the signs and symptoms of anisotropia present their natural appearance. — (*See Anstretes*, b. 2, p. 141.) Fourth degree of anisotropia is noticed by Richter as the most interesting to the history of anisotropia, anisotropia being a constant affection of nature, many of which, however, continue to avoid service by presenting to them under a disorganization which they well know does not necessarily produce any very considerable alteration in the natural appearance of the part affected. Thirdly, while the disorder is only in the stage of weakness, the patient always complains of constantly multiplying vision, or of the vision immediately or retrogressively. Fourthly, anisotropia forms appear before the eye, especially as the disorder, even when the patient is entirely blind. Fifthly, the disorder of vision goes on to complete blindness, without any morbid interruption, or retrogression directly, when both the eye is quite blind, and the eye-sight on the other side is perfectly undisturbed, there is one infallible symptom of this anisotropia; namely, if the sound eye be very carefully covered, the pupil of the blind eye immediately expands, and the iris becomes opaque, anisotropia, notwithstanding the diseased eye be exposed to the strongest light possible. However, this criterion is mostly failing, because the anisotropia, qualified with any perceptible effect, except loss of vision, is seldom confined to one eye, but usually affects both. — (*See Lectures des Anstretes*, b. 2, p. 441, 442.)

Mr. Travers divides anisotropic affections into two classes, the organic and the functional. The first comprehends situations, however induced, in the texture or position of the retina, optic nerve, or choroid. The second includes expansion, or loss of function of the retina and optic nerve, depending upon a change, either in the action of the vessels, or in the state of the secretory apparatus.

As marks of organic anisotropia, Mr. Travers enumerates, 1. Lesions, extravasation of blood, inflammatory deposit upon either of its surfaces, and loss of transparency of the retina. 2. Morbid growth within the eyelid, choroid, staphy, and all such obstructions as directly oppose or derange the texture of the retina. 3. Apoplexy, hydrocephalus, aneurysm, or abscesses in the brain, or in or upon the optic nerve, or its sheath, and thickening, expansion, absorption, or distention of the latter. As causes of functional anisotropia, Mr. Travers specifies, 1. Temporary derangement; vascular congestion, or vacuity, in those vessels or cerebral trunks; expansion or distention of extensive membrane, as of the liver, kidneys, uterus, intestines, and lungs; various forms of injury and disease; and sudden transitions of morbid morbid action. 2. Functional derangement, expansion or contraction of muscular power from various constitutional and local causes; from causes common or exclusive of the visual faculty; and from the general or local action of poisons on the nervous system, as lead, mercury, &c.

From the description, says Mr. Travers, it will be understood that organic and many forms of functional anisotropia are incurable; and the functional, by continuation, lapses into the organic class.

Functional anisotropia is subdivided by Mr. Travers into, for the Sympomatic, or that which is only a symptom of some general disease, or disorder of the system; and, for the idiopathic, or that which is the sudden transition of the visual action from another organ of the body; as, for example, from the skin, the testicle, &c. — 340, the Idiopathic, or that which depends upon a peculiar condition of the retina, or, for example, the Sympomatic, anisotropic vision. — (*Synopsis*, p. 122—124.)

On the whole, extreme local atrophy, that is to say, a depression or total loss of the eyeball, associated with any other organic local or constitutional defect, may be said to be a very rare case, the disorder being usually more or less complicated.

To the local complications, *viz.* flux, buphthalmia, cataract, glaucoma; a general various state of the vessel (anæmia, hyperæmia; exophthalmia; atrophy of the eye; encephalitis in the organ and surrounding parts; paralysis of one or more muscles of the eye; epiphthalmia; lepta; pseudos of the eyeball; epiphthalmia or proptosis; and internal epiphthalmia in particular; a vascular buphthalmia of the eye (buphthalmia, buphthalmia); and finally, wounds or contusions of the eye or adjacent parts. With these cases should also be mentioned that important case, *Empyema* of the eye. From this simple enumeration of local processes, those two may be more frequently associated is only a symptomatic effect of another disorder of the eye, with which it is connected, and how often it is connected with the same diseases, namely which germinate another or several other diseases of the eye.

Among the general complications, first, *Intemperance* (those which are purely nervous) impairment of the health in various forms by infection, contagion, or miasmata; a bad habit of body; typhoid fever, the anæmic effects of which upon the eye the author of this work has frequently noticed; malaria; internal and external hydrophthalmia; organic diseases of the abdominal viscera; worms; cholera; consumption; old diseases of the legs; organic disease of the brain and skull; complications arising from pregnancy; leucorrhæa, &c. In these general complications, first remarks that the mutual connection between atrophy and some remote disease of another organ, or of the whole constitution, cannot be mistaken; and in these cases we often see the disease of some other distant part from the eye suddenly or gradually diminished, and immediately appear again as a sympathetic action in the form of amaurosis, of which the most remarkable instance is seen after the sudden healing of old sores of the legs. (Barr, *Lehrbuch Augenkr.* 2. 2. p. 423.)

From the above general remarks upon atrophy it is quite manifest that the symptoms of the disease vary considerably according to the violence of its causes, and of the local and general complications, though the seat of the disease and what is particularly the progressive course of the loss of vision be in the optic nerve; and it strikes especially to the nature of the causes, whether it is that the disease appears to take place in the eye.

It may consider as the only really inoperable symptom of atrophy that weakness of sight (asthenopia), or that complete blindness, in which neither with the increased or unusual eye the loss of sight can be perceived in the structure and shape of the affected organ. Hence, first, the most important of vision or blindness, amaurosis. But how rarely this complete symptom is met with alone, and how frequently it is connected by some other defect in the structure and form of the eye, is proved by many examples.

The accidental symptoms of amaurosis have, however, not been as yet consisting of a considerable distortion of the pupil, and immobility of the iris, because these symptoms are rarely the most frequent; but, as Barr observes, this is another proof that ignorance has prevailed respecting the true nature of that disease of the eye and its modifications, which are usually termed amaurosis.

The accidental symptoms of amaurosis may consist in the faulty size and shape of the pupil. It may cause the pupil to be very much dilated, anæmic, and possess its natural black colour and usual transparency. It cannot be denied that this is the state of amaurosis most, but it is equally true that there are many exceptions. Sometimes, according to Barr, in the most complete and anæmic cases the pupil is of its proper size, and even capable of free motion (Thiersch, *Klinische Periodische*, &c. 1. 2. p. 319; and occasionally, it is actually smaller and more contracted than natural. This latter often sometimes extraordinarily large in the most light. And it is well known that it is unusually small in every kind of atrophy. (Krause, *Reinhold's Handb.* 2. 1. p. 573. Humer, *Augenkr.* &c. 2. 2. p. 414. Barr, *Lehrb.* &c. 2. 2. p. 423.) According to the latter writer, the pupillary edge of the iris partly has its proper shape, being generally more or less angular, either at such considerable point, or

above and below, so as to resemble a worn hammer the edge of the iron part; or towards the lower or upper, so as to have a serrated or toothed in the form of the pupil of a mummified animal. These appearances are highly important, having great influence over the diagnosis.

Frequently not only the size and shape of the pupil are faulty, but the position of that opening is quite abnormal, being inclined either upwards or downwards, or sideways or forwards, but most commonly in a diagonal line between upwards and forwards, and in these cases the pupillary margin of the iris never describes a regular circle, but is always more or less angular. (Barr, *ibid.* 2. 2. p. 423.)

The pupil of an eye affected with amaurosis frequently does not exhibit the clear shining blackness which is seen in a healthy eye. It is found that it is of a dull, glassy, horn-like blackness, which anæmiatization is frequently enough to suggest a well-informed practitioner of the nature of the disease. It is in the words of Mr. Thiersch, "little more than the healthy appearance of the iris in the eye of a horse." (Synopsis, p. 180.) Sometimes the colour of the pupil has an inclination to green; while in other examples this anæmia seems to be dense, white, and cloudy, so that the complaint might easily be mistaken for the beginning of a cataract. The error into which inexperienced surgeons are liable to fall, may generally be avoided by attention to the following circumstances:—The iris appears to be not smaller, and behind the pupil in the place of the crystalline lens, but more deeply in the eye. Nor is it in proportion to the impairment of sight, the patient being quite blind, while the iris appears to be so small, that it is a great pity that the opacity of the crystalline lens, it could at most only receive a slight weakness and obscurity of vision; at the same time, Richter acknowledges that it must be more difficult to avoid mistake when a beginning amaurosis is accompanied with the conditions of atrophy, and consequently when the degree of blindness seems to bear some proportion to the degree of opacities in the pupil. However, in this case he maintains that the true nature of the disease may generally be known by considering the ordinary symptoms of the two diseases. (Anderson, 2. 2. p. 140.) And, according to Barr, when the pupil is of a true dark grey, or greenish-grey colour, a lateral inspection of the eye will show plainly enough that the darkness is in the vitreous humor, and behind it. Sometimes the pupil appears reddish, quite red, or of a yellowish-white colour (Krause von den Augenkr. 2. 2. p. 413; while in other cases the interior of the eye a good way behind the pupil seems quite white, and a concave high-convex surface may be observed, upon which the ramifications of blood-vessels can be clearly seen. In particular instances the vitreous humor behind the whole back part of the eye, while in other cases it only occupies a half or a small portion of it. This peculiar appearance has been described to a loss of transparency in the vitreous itself, and a consequent reflection of the rays of light. (Haller, *Memorie*, Paris, 1763, 5. p. 409. Mr. Thiersch is contrary to the opinion, that it arises from a deficient secretion of the choroid plexus, a pre-matural adhesion between the choroid coat and the retina, and a dislocation or prolapsus appearance of the latter from the same. (Synopsis, p. 181.)

One of the strongest characteristics of amaurosis and an insuperable obstacle, and one most to be depended upon, in practice, is reported by Mr. Thiersch, to be the difference which declares of a visible surface at the true surface. In frequent contact it appears as if a new surface is generally diffused, and most or little about, which increases with the darkness of the light; but in amaurosis a kind of transparency is noticed or emanates from the iris, the flame seeming to be split, when it is examined. (On the Nature, &c. of Amaurosis, Lond. 1811.)

There can now be no doubt that the whitening behind the pupil is sometimes here originated from the diseased state which, in cases of atrophy, the iris of the eye acquires from the deeper part of the organ, and gradually moves its way towards the iris, being always attended with loss of sight. Putting out of present consideration the change of colour within the eye, produced by foreign humors, the above colour changes behind the pupillary coat confirm, as Barr supplies, in very old cases of amaurosis, because the alteration is observed by Schaeffer as taking

plate especially in examples the formation of which was quite sudden. (Vernieuw den Hart, *Scotth.* ii. 3. and Langenbeck has recorded cases in which the same appearance happened in the early stage of the disease.—(New Nat. Hist. p. 46, &c.)

Besides the above appearances of the pupil itself, and of the pupillary margin of the iris, there are also several important phenomena with respect to the action of the iris. Sometimes the iris passes but very slowly, and frequently not in all, though the light be strong, and the upper eyelid be raised over the eyeball. While in other examples a very moderate light will bring on such a rapid contraction of the iris and closure of the pupil, as we never witnessed in a healthy eye.

We have also the authority of Boerhaave for asserting, that in particular instances the eye not only possesses the power of action, but is capable of seeing with uncommon activity, as even in a very moderate light, it will contract to an unusual degree, and nearly close the pupil.—*Amstelred. Ges. Wondur.* b. 3, p. 134, edit. 1785.

Two or three remarkable instances of the latter stage of the iris, in cases of amaurosis, were some years ago shown to me by Dr. Alibert, then staff-surgeon at the York Hospital, Chelsea, and I have seen other similar cases in St. Bartholomew's Hospital. Most of the patients in question had not the least power of distinguishing the difference between total darkness and the visual light of the sun, or a candle placed just before their eyes. Justa sometimes found the pupil capable of motion in this disease, and Schaeffer once noticed the same thing.

Such cases, Mr. Travers thinks, can only be explained by considering the organ to be sound, and the cause of the disease remote or external to it. Thus, says he, in a case of vitreous tumour, compressing the left optic nerve, immediately behind the ganglion opticum, although the vitreous was opaque, the iris was active. In two young ladies, in whom the eyes, as in the former case, were perfect, and the blindness temporary, the iris was even vigorous; and there was the strongest presbyopic evidence from the symptoms that the amaurosis was in the cerebral portion of the optic.—*Opuscul.* p. 128.

In some instances again, when the strength of the light is unusually increased, the pupil expands with more or less slowness.

I have already alluded to the occasional numbness of the iris, notwithstanding the insensible state of the retina. Let me now take notice of a case which sometimes presents itself, and is quite the reverse of this last. The nerves of the iris may be paralytic, while those of sight continue unimpaired. Schaeffer was acquainted with a woman whose pupil was unconsciously dilated, and totally incapable of motion. Her sight was very weak, and sometimes says of no use to her. She could scarcely discern any thing by day or in a strong light, but she could see rather better at night and in dark places. This indistinct sight depended upon the dilated, paralytic state of the pupil, by which too many rays of light were admitted into the eye; and the reason why the patient could see better at night was because the pupil, in its natural state, always becomes contracted in a dark situation.—(See Vermeulen's *Charaktere Schaeffer*, von J. L. Schaeffer, *Med. Z.* p. 12, 13.)

On this curious part of the subject it is remarked by Mr. Travers, that if the retina be inactive, compressed, or unsupported, the iris mechanically dilated, or the optic nerve paralysed, the pupil is inactive, independently of the state of vision. In the first of these cases it is evident vision will be lost; but we occasionally see useful vision combined with the second and third, as they sometimes in which the iris has been half destroyed or has become preternaturally adherent, or is malformative where it is half wanting; and in particular of the vitreous serves accompanying plans.—*Synopsis*, p. 128.

Frequently, in amaurosis, when the sight of only one eye is lost, and the other retains its full power of vision, not the slightest defect can be discovered as long as the patient keeps both of them open; but the instant the second eye is completely covered, the iris becomes perfectly featureless, the pupillary margin assumes an angular shape, and the pupil expands, being sometimes evidently drawn towards the edge of the cornea.—(Boer, *Lectur. von dem Augerkrank.* 4. 2, p. 425. This

demonstrates the difference between the independent and the associated action of the iris.

Besides the above appearance of the pupil and iris, amaurosis is attended with other characteristic phenomena, which occur under certain circumstances, in the form, texture, and state of other parts of the eye and adjoining organs. Thus the patient often complains of a peculiar treacherous dryness of the eye, or of a sensation as if the eyeball were about to be pressed out of its socket; and indeed, says Boer, one may sometimes find a grating noise, and distinguish a fluctuation in the orbit behind the eyeball, when this organ is pressed upon by the finger, or moved in various directions, though neither its movement nor its enlarged, nor any tendency to exophthalmos, be really present. Nor is it very uncommon to find the affected eye preternaturally hard, soft, or even quite flaccid; but it is less common to find the dimensions of the globe of the eye increased, or the organ affected with atrophy.—(Boer, *loc. cit.* p. 425.)

However, in opaque amaurosis, as Mr. Travers notices, a peculiar bluish grey tint of the sclerotic coat is frequently observable; and sometimes even a degree of bulging on one or more sides of the eye, or simply a loss of sphericity, is also appearing flattened.

A consequence of the superficial vessels, especially of the long blood-vessels of conjunctival origin, is likewise another symptom, frequently observed in cases of opaque amaurosis.—See Travers's *Synopsis*, p. 145.

The same gentleman also gives the particulars of a disease, in which a case of amaurosis was attended with a collapse of the retina from absorption of the vitreous humour.—*Op.* *loc. cit.* p. 136.

Some of the peculiar marked effects of amaurosis have been already described in speaking of the several defects of vision, which accompany an inactive weakness of sight. Besides these, however, there are others which merit attention. For instance, the patient feels in the eye and surrounding parts an intense sensation without any visible pain, and complains of a remarkable sense of fulness or weight in the sight. Amaurotic patients are also frequently attacked with sudden violent giddiness, usually ending in a considerable disturbance of the sight, and sometimes in severe general headache. Occasionally they fancy that small objects at first are lodged under the eyelids, and are fearful of moving these parts of the eye. It is also well known, that many persons become insensible while labouring under severe haemorrhage, extending from or to the diseased eye; while, at other occasions, the most violent pains are confined particularly to the region of the eyeball, and have the appearance of being strictly periodical. In certain other cases the pain is wandering, and shoots in every direction about the eyeball. These painful feelings often precede the amaurotic blindness a considerable time, and often first take place when one or both eyes are nearly blind; but the pains and loss of sight are not necessarily produced together. Lastly, some patients are not well, in whom the worst pains only last until the amaurosis is perfectly formed, when they gradually and permanently cease. In all these painful cases of amaurosis, the pain and the blindness chiefly depend upon the same cause, and one is seldom the occasion of the other. Sometimes amaurotic patients experience very violent pains, that they lose their senses and grow delirious; but in these cases, if we can credit the statement of Boer, important mental changes in the basis of the skull, or the brain itself, are invariably noticed after death.—See *Lectur. von dem Augerkrank.* b. 2, p. 429. In some amaurotic patients intense symptoms may be remarked in others, sometimes; and more rarely still again in all its degrees, either as a transient or permanent affection.

According to the observations of Mr. Travers, pain affecting the forehead and temples is a necessary symptom of amaurosis, depending in proportion to the degree of blindness. When the amaurosis is perfect, it usually ceases altogether, if the disease has its seat in the eyeball. But when the pain is severe, remains imperfectly, and is quickly renewed worse by exercise, it is usually connected with organic disease of the brain. In that case derangement and error of the nervous system, look of strength and heat, disposition to anger, occasional confusion of intellect, impatience to exertion, and paralysis of one or more members will be consistent symptoms.—*Synopsis*, &c. p. 167.

Paralytic appearances may precede amaurosis, either in the vicinity of the eye, or in the annulus of the face, or in a distant situation, as the extremities. Sometimes they accompany the disease, and sometimes closely follow the weakness of sight, being not necessarily the forerunners of a fatal attack of apoplexy.

In the acute or convulsive symptoms may be combined with amaurosis, and when they arise occur in the complete stage of the latter disease. Their prognosis (like a very unfavorable one) for the patient's life.

But according to the same experienced oculist, when it is a case of perfect amaurosis several of the external senses are affected; and lastly, when the internal senses begin to suffer, when, for instance, the hearing, and then the smell and taste are lost, and afterward the memory and other intellectual powers fail, the patient's speedy dissolution may be expected.—(See *Lectures on the Diseases of the Eye*, 2, p. 351, Wm., 1857.)

As Professor Ross correctly observes, age cannot be considered a predisposing cause of amaurosis, as it is of cataract; for there are many many blind persons who have been deprived of their sight by amaurosis in their best days than old persons thus attacked. Amaurosis spares no age—not even the new-born infant. Mr. Lawrence, in his *Lectures*, contrasts in this respect, adding his opinion, however, that amaurosis is very frequent during the active middle period of life, and very common about the cessation of menstruation in females, and the corresponding age in the male.

Four forms of congenital organic amaurosis are noticed by Mr. Travers. One in which the eye is preternaturally small, wet, and even closed; the iris translucent, and not influenced by belladonna; and the globe affected with tremor, and not under the control of the will. A second, depending on a deficiency of the pigmentary system; the iris is translucent, strong light produces amaurosis, and vision is limited and confused. The vessels of the choroid give the interior of the eye a coppered tinge. A third case is that in which the sclerotics is encrusted upon the cornea, that the latter is scarcely wider than the pupil. In the fourth kind of congenital amaurosis, described by Mr. Travers, the eyes were in contact, as if attracted by a faint perception of light; but the pupil is fixed, no marks of organic degeneration can be seen; but Mr. Travers apprehends that the disease must be associated with a marked state of the mental or optic nerve.—(See *op. cit.*, p. 153, 351.)

Another does not see, but does appear to have any perception of the objects of the compass; but it would seem that dark eyes, especially those which are called black, are more disposed to amaurotic blindness than such as are light-colored. According to Ross's expectation, the eyes may in this eye affected with amaurosis, have an iris of a dark-brown, or dirty brown or black even here, diseased. In the peculiar constitution of the eye, then, as well as in a strabismus and choroid transposition, there exists a tendency to the disorder.

More frequently than cataract, amaurosis is found to be a hereditary disease.—This is so much the case, that most of the members of a family for many that one generation may lose their sight from blindness at a certain period of life. There are that he is acquainted with more than one family in which this has happened, and what merits attention, the women of one of these families, down to the third generation, became completely and permanently blind from amaurosis on the cessation of the menses, while all the others who had had children were unaffected. But the father of this unfortunate family, who as well as the females have very dark brown eyes, all seem to be weak-sighted, though none of them are yet blind.—(Lectures on the Diseases of the Eye, 2, p. 442.)

In women, especially those with black eyes, the time when the menses stop is a dangerous period for the commencement of amaurosis.

According to the same writer, patients whose vision went to blind gradually for a long time, but who were suddenly stopped, and whose eyes are dark, are very liable to amaurosis.

One of the less common causes of amaurosis is an aneurysm, or aneurysm in this or that part of the retina, or in the optic nerve, or in the part that carries the optic nerve. This is to be followed by the gradual weakness of sight, or the pain, headache, which comes on at the very commencement of pregnancy, and sometimes after

delivery, but always attended with dyspnoea and other probable vomiting. This species of amaurosis, however, should be carefully distinguished from that which sometimes occurs in the last stages of pregnancy, and chiefly from among the long-sustained interstition of blood in the head and eyes, particularly when the bowels are at the same time loosed, and the patient comatose. This latter case usually continues till after delivery; or if the uterus is relaxed, difficult, and attended with considerable efforts, the symptoms may then attain its complete form at the time of delivery, and not afterward.

There was a young woman, who, at the very beginning of her first labor, progressed, which followed each other quickly, regularly lost her sight, becoming completely insensible between the third and fourth months, but in the first two months she continued blind till after delivery, but in the third instance the power of vision never returned at all. Her vision had under her care another system, who was attacked with amaurosis whenever she drank chocolate; but upon leaving off that drink, she never afterward had any complaint in her eyes.

If we are to believe the generality of writers on this subject, the abuse of better stimulants, as of chocolate or coffee, better and better, and better medicines, especially quinine, is undoubtedly a predisposing cause of amaurosis.

The abuse of mercuric preparations sometimes may in direct amaurosis; amaurosis does of course, by the way; belladonna, &c. Last will do the same thing. Respecting the operation of some of these causes, however, Mr. Lawrence entertains a doubt. The mercuric preparations tend to dilate the pupil, he observes, are supposed to give a tendency to amaurosis. He has never seen such an effect produced by the belladonna; and he adverts to one case in which it was used a great length of time. The effect of writers seems to him equally problematic.

One not unimportant and very important cause of amaurosis is hysteria and hypochondria, with which must be mentioned infatuation, and disease of one or more of the abdominal viscera, especially the liver.—(See *op. cit.*, p. 351—446.)

According to Richter, the causes of amaurosis may be properly divided into three principal classes, the diagnosis of which indicates three general methods of treatment.

The first class of causes depends upon an extraordinary plethora and turbidity of the blood vessels of the brain, or of those of the optic nerve and retina, upon which last parts a degree of pressure is thereby supposed to be sustained. A considerable plethora, especially when the patient feels himself, or feels his head very heavy, and frequently notices the appearance of black specks before the eyes, and sometimes complete blindness. A plethoric person (says Richter) who held his breath, and looked at a white wall, was conscious of observing a kind of net-work which immediately appeared and disappeared with the dilation and contraction of the arteries.

Richter thinks it likely that the disease in three patients, when it proceeds from the stagnation of blood in the vessels of the brain, not being blind according to custom, the suppuration of the menses, and the cessation of menstruation from place. In the same manner the complaint may be brought on by great bodily exertions, which must determine a more rapid current of blood to the head. Richter refers to a case of a man who became blind all at a sudden, while engaged in a heavy burden up stairs. He tells us of another man, who labored excessively hard for three days in a workshop, and became blind at the end of the third day. Pregnant women in like manner are sometimes bereft of their sight during the time of labor. Richter has received a remarkable instance of this in a young young woman, thirty years old, and of a full habit. When she was pregnant, she was troubled with violent sickness all the time of delivery, so that nothing would stop in her stomach. She was blind three or four times without effect. Towards the ninth month her sight grew weak, and her sight on the day before parturition, she was quite blind. The pupil of the eye was greatly enlarged, but retained its orange black appearance. She recovered her sight immediately after delivery, and did not suffer any particular complaint. Richter remarks on this that he has been three times a

witness of this extraordinary circumstance.—Verworn's *Chir. Schenkel*, 1861, p. 6, 1864, 1866.—Richer speaks of a person who lost his sight during a violent fit of vomiting. Schenkel argues that it is not uncommon for soldiers, who are performing forced marches in hot weather, to lose their sight all on a sudden.

Now this coincides with Schenkel, Richer, and others, in regarding as a frequent cause of amaurosis repeated and long-continued depletions of blood to the head and eyes, produced by various circumstances, viz. by pregnancy; a tedious and difficult labor; lying and carrying heavy loads, especially with the arms raised up; all kinds of work, in which the eyesight and ocular faculties are intensely exerted, with the head bent forward, and the abdomen compressed, as is the case with shoemakers, tailors, &c.; every sudden stoppage of natural or unnatural long-continued passages of blood, so that of the venous, arterial, or hemorrhoidal; the cessation of habit and sometimes of more particular action of the ear; severe and obstinate vomiting; febrile action in hot dry weather; sunstroke and other swellings of considerable size in the neck, pressing upon the jugular veins, and obstructing the return of blood from the head; the use of a pedicure, or wax bath, the water of which is of high temperature; hard drinking; violent gusts of passion; dropped and excessive over-dieting; and hard smothering at food. These causes are most likely to occasion amaurosis in proportion as the individual is young and phlegmatic. The causes of this amaurosis, which is characterized in its first stage by increased sensibility of the eye, and expiration of life, are noticed by Professor Moir in strabismus which produce a long and repeated determination of blood to the head and eyes.—*Reich, Lehrb. von den Augen*, b. 2, p. 495 and 500, &c.

Mr. Lawrence, in his *Lectures on the eye*, remarks, in its most frequent and important form, that which is seated in the eye itself, is precisely the most difficult to treat, on account of the structure; including under this those of degrees of increased vascular action, whether dependent on filaria, syphilis, arteritis, &c., or on inflammation in its internal and most, and the most common cause of inflammatory diseases, that is, serous change permanently destroying the structure of the part. When, says Mr. Lawrence, we advert to the structure of the retina, we again suppose that it would be labor in vain to effect; we find it composed of minute ramifications of the retina covering the eye, and in that network of vessels the nervous pulp is deposited. The state of the retina, when situated after death, in amaretic eyes, reveals manifest disease; it exhibits those changes which are continued, independently of disease, until death, it has been found discolored, opaque, watery, half-colored, tough, and in some cases even melted. The preceding doctrine is, however, judiciously qualified by its restriction to the disease situated in the eye itself. The retina and optic nerve, Mr. Lawrence affirms, with other surgeons, may be diseased sympathetically, so the stomach may be diseased without any change visible in the retina.

The second class of amaurosis supposed to operate by mediating either the whole body or the eye alone, and may include the general or local use of toxic materials. In the first case, the weakness appears as a symptom of considerable general debility of the whole system; in the second case it is altogether local. Every great general weakness of body, let it proceed from any cause whatsoever, may be followed by a loss of sight. Amaurosis, if we can give credit to the opinions of Richer, is sometimes the consequence of a tedious diarrhea, a violent violent fever, profuse hemorrhage, and hemorrhoidal discharges.—Also Verworn's *Synopsis*, p. 144. Richer refers to a debilitated woman, who became blind on the sixth hour after delivery. According to the same author, we find weakening causes operate upon the eyes, and occasion blindness, as powerfully and often as premature and excessive indulgence in venereal pleasures. Mr. Lawrence, in his *Lectures*, does not coincide at some of the foregoing views. "I think," says he, "who have regarded amaurosis as arising from debility, have overlooked the facility and ease of the cure, may be produced by all those circumstances which debilitate the system generally,

such as loss of blood from profuse hemorrhage, diarrhoea, copious discharges, &c. I have never seen amaurosis produced by such causes. That general debility and grief may throw the sensibility of amaurosis, I am inclined to allow; for it is not improbable that across expressions of that kind may produce inflammatory excitement in the brain or eyes; but I think we cannot without good direct proofs, ascribe the influence of debilitating causes generally to the production of amaurosis. The most clear instance of any directly debilitating cause producing amaurosis, is that of protracted suckling."

The causes which operate locally in weakening the eyes are various. Nothing has a greater tendency to debilitate these organs, than keeping them long and attentively fixed upon minute objects. But however long and sensibly objects are viewed, if they are diversified, the eyes suffer much less; than when they are all of the same kind. A frequent change in the objects which are looked at has a material effect in strengthening and refreshing the eye. The sight is particularly injured by looking at objects with only one eye at a time, as is done with telescopes and magnifying glasses; for when one eye remains shut, the pupil of that which is open always becomes dilated beyond its natural diameter, and lets an extraordinary quantity of light into the eye. The eye is generally very much hurt, by being employed at the close inspection of brilliant, little-colored, shining objects. Among the occupations recommended by Mr. Verworn as particularly exposing persons to amaurosis, are those of needle-workers, writers, draughtsmen, inspectors of linen and woven cloths, and of new banknotes; money counters, watchmen in iron-furnaces and glass-furnaces; tavern-cooks, watchmakers, engravers, philosophical instrument makers, and others, &c.—*Synopsis*, p. 144.—They are greatly mistaken, says Richer, who think that they save their eyes, when they illuminate the object which they wish to see, the evening with moon light, or with a lamp that intercepts and collects all the rays of light, and reflects them upon the body which is to be looked at. Richer mentions a man, who, at the middle of winter, went a journey on horseback, through a snowy country, where the sun was shining upon bright snow, and was attacked with amaurosis. The speaker of another person, who lost his sight in consequence of the chamber in which he lay being suddenly illuminated by a vivid flash of lightning. A man was once seized with blindness, while his eyes were fixed on the moon, in a fit of great emotion. Richer also mentions the belief, that a concussion of the head from external violence, may sometimes operate directly on the retina, so as to break and render them completely paralytic.

Richer observes the following statement; but, he says, among the most important causes is to be considered every abuse of the eye itself, especially its dissipated position, as a long and close inspection of one object, particularly with a microscope, when the thing examined is very brilliant or reflects back much light into the eye. Hence the use of pencils of light, and long gazing through camera obscura &c., are conducive to the disease. In this respect, every kind of ray or heat which strikes the eye itself, and reaches the retina, is to be considered as a cause of amaurosis.—See also Verworn's *Synopsis*, p. 144. Thus, recommending lamps, like Argand's, the view of a white wall illuminated with lantern's rays; and holding a long white stick at the eyes, or pasting especially the sun, with the unassisted eyes, are circumstances likely to bring on the disease. That a flash of lightning, especially when it suddenly strikes a person at the sight out of a post-hole, may produce an amaurotic condition of an irritable eye or even perfect blindness, is a well-known fact, and it is on the same principle that going suddenly out of a dark house, immediately after waking in the morning, into an apartment that contains an open candle, or person, is liable to hurt the eyes, though the time elapsing may only be very short. There is also to be included every kind of over-excitation of the eye by light, as happens to blind patients, when they lie with their eyes open all the day in a large sunny chamber.

Very often the cause of amaurosis proceeds in local or constitutional debility, proceeding from impairment of the nervous power, or of the power of the blood, especially those of the cerebral and systemic; either

Does a constriction of the visual nerve, arise from a considerable length with the weight of the whole body upon the head; constriction of the eyeball, sometimes caused by violent sneezing, but more generally by constriction of the eye with warm vapours, &c. Some of the cases of amaurosis seen below in the temple of the eye, observed by Mr. Travers, were associated with signs of disorganization; some were superficially inflamed; and others presented no external appearance of injury. We learn also from the same authority, that it is not always the eye on the struck side of the head that is affected.—*Opuscula*, &c. p. 152. If we are to believe Beer, and other foreign practitioners, considerable direct weakness may arise from cholera, jaundice and diarrhoea, starvation, and the violent spasm of influenza and hoarse; bleedings; impetuous kicking of the children; excessive indulgence in luxury, and the over-employment of intellect. A general debility, which has the most effect on the eyes, may also arise from long trouble, especially when the diet is poor and food; also from a deficiency of proper food; long watching; violent and violent fight; impetuous reading the eyes with very cold water, especially when they are already weak and irritable; and keeping them long in a dark place, particularly when they are thus situated a good deal in some picturesque mode of labour, a case which, Beer says, is very frequent in Venice. The amaurosis following typhus, whether any unusual irritation of the eye by light. Beer also notes the general debility.—*Lectures von den Augen*, &c. 2, p. 466, &c.

Like nervous febrile cases Mr. Travers, amaurosis sometimes follows typhus and vesicular fever, and the various forms of acute constitutional disease. He has several times met with it as a consequence of influenza fevers. He observes that it is also sometimes a consequence of chronic wasting diseases, which organic changes interrupt the nutrition of the system. He has seen a rapid and severe atrophy sustained for a chronic affection, and when disease had previously affected the eyes, *hemeralia* in both.—*Opuscula*, p. 153.

With regard to the doctrine that certain forms of amaurosis are diseases of debility, Mr. Lawrence expresses his dissent in its corporeity, and asserts, that the only scientific and successful treatment of amaurotic affections is found to be stimulative. Whether the atrophy resulting from typhoid fevers, of which I have seen several instances, proceed from debility, or from too great a determination of blood to the head, may admit of dispute; but I conceive, that in many of such cases, toxic treatment is clearly indicated, if not for the eye itself, certainly for the generally enfeebled state of the health, which the amaurosis is connected. Yet Mr. Lawrence's doctrine, that debility and weakness of the vessels originally lead to the amaurotic affection, may be more correct than the theory which refers the blindness simply to weakness. However, as the amaurosis generally does not show itself till an advanced stage of disease, or that of great debility, and as it only ceases as the patient regains strength, it can hardly be considered as a case in which any other treatment than rest is to be avoided. It is right to state that Mr. Lawrence himself, notwithstanding his belief in amaurosis being a kind of inflammation of the retina, modified the antiphlogistic treatment according to the state of the constitution.

The third class of eyes consists of strabismus, most of which are asserted to be in the oblique muscles, whence they correspondingly operate upon the eyes. The government of Haller, Boisson, and Schramm; all tend to support this doctrine. Many aphakic subjects are found to have suffered with tremor and laceration, or even atrophy by repeated squintings, trappings, and other means, which have manifested themselves in the same manner and the defective functions in general. Haller tells us of a man who lost his sight, a few hours after being in a violent passion, and recovered it again the next day, upon taking an emetic by which a considerable quantity of bile was evacuated. A woman is also cited, who became blind whenever she was troubled with what are termed verticils in the stomach.—(*See Analses des Wundarben*, b. 3, cap. 14.) However, according to Beer, impetuous amaurosis seldom depends upon disorder of the gastric organs, excepting the rare few cases. (*Lectures von den Augen*, b. 2, p. 456.) a very important difference from the sentiments entertained by Schramm, Richter, and

Boerhaave. The close sympathy between the stomach and the eyes is well illustrated by a case recorded in some of the journals, and referred to by Mr. Lawrence in his Lectures. It was an amaurotic man, fixed pain over the epigastrium, it is said. It was not tolerably passing and other digestive functions: an eructus was at the given; and under its action a loud was rejected from the stomach, and the amaurosis immediately disappeared.

Amaurosis sometimes proceeds from mechanical irritation. A wound shot almost the upper eyelid, and lodged at the upper part of the right orbit, between the eyelid and eyeball, so that it could be felt externally. The patient shortly afterwards became blind in the left eye; but recovered his sight after the removal of the shot.—*Analses des Wundarben*, b. 3, p. 424.

According to Beer, several constitutional disorders, but more especially gonorrhea, are deeply concerned in the production of amaurosis. Whether these Beer's theory of what he terms gastric amaurosis, will naturally doubt the existence of the theory; and Mr. Lawrence himself asserts, in his Lectures, that he has never seen such a case, or that it is not necessary to refer to the effects of the nervous structure of the eye. It is not because amaurosis sometimes occurs in gonorrhea or rheumatic affections, that the affection of the sight is necessarily of a gonorrhea or rheumatic origin; for the fact itself proves, that such constitutions are not exempt from the risk of being attacked by disorders of the eye. Mr. Lawrence has also observed, any case, in which the signs of amaurosis could be referred to any other cause.

Regarding the causes of amaurosis, the following remarks by Beer claim attention. Various swellings to the eye, as, for instance, enlarged tumours, oedema, hydrophthalma, the death of the optic nerve, may and must gradually produce complete amaurosis by their pressure upon the optic nerve and retina. Some of these cases are usually characterized by a protrusion of the eye from the socket.—(*See Encephalitis*.) In Mr. Lawrence's system is a question of two anastomotic eyes, in which the optic nerves are struck at about one-third of their natural size. Similar instances are recorded by Dr. Mead.—(*See Wundarben*.) According to Mr. Lawrence, Mr. Lawrence has also seen interesting specimens of enlargement of the third ventricle, the pressure of which he says is in some upon the optic nerves, and thus to account for the amaurosis under which the patients laboured.

In the same manner different morbid changes in the brain itself, and in the bases of the cranium in particular, may be the direct cause of amaurosis; for example, hydrocephalus internus, cancer, and aneurysm at the base of the skull.

Just as aneurysms is frequently a very symptomatic effect of various disordered states of the constitution, so may different morbid changes, commenced in the eye by these states of the health, become the immediate cause of amaurosis. As hydrophthalma, encephalitis, cancer, leucorrhoea, dislocation of the vitreous humor, &c.—

From a contagious atmosphere, which is generally injurious to the eyes, an amaurotic blindness may originate, though but very rarely, and as it would pass, only through the powerful influence of such cause, of the air over the whole singularity and nervous system. Destituted, nervous, weakened persons, by remaining long in the atmosphere of a party (Cham, Médec. de Paris, 1771, lib. 2, art. 5, and Boisson, De Morbis Animi, p. 12), that of a damp cellar, or exposed to other effluvia, may be suddenly attacked with amaurosis; and Beer asserts, on that his experience confirms the truth of these reports.—(*Lectures*, &c. b. 2, p. 424.) A sympathetic affection of the nerves of the eye, with a various picture in the upper part of the eye, is one of the most frequent causes of amaurotic blindness.

Atropine, not yet fully considered, and very like the antispasmodic, consists of an homogeneously dissolving secretion of the pigmentary system from the retina hydrophthalma, rheumatism, and eyes, which secretion, in some individuals earlier, and more considerably, in others later and in a slighter degree, coincides with other symptoms of a different nature.—(*See Boerhaave's Lectures von den Augen*, b. 2, p. 151, &c.)

As Mr. Travers has correctly explained, the history and concomitant appearance of amaurosis, usually

But the adoption of some original method of treatment; but, declares Beer, no to the patient whose surgeon, under these circumstances, derives from a heap of what are considered remedies for anæmia, as from a lottery, the first as the best?

In order to avoid this erroneous method, and not render a half-blind person completely blind, instead of improving, or at least preserving, whatever amount of vision there may be, the surgeon should act with great caution, and constantly bear in his mind, first, the symptoms, sex, and age of the patient; secondly, his ordinary employment, and general mode of living; and, thirdly, the principal morbid appearances under which the anæmia originated and was developed.—(Beer, *Lectures on the Diseases of the Eye*, 2, p. 306.) But what will be the prudent anæsthetic as a correct acquaintance with the anæmia, the anæmia in general, and the contraindications under which the use of this or that particular remedy is likely to be useful or detrimental. I know of no writer who has been so minute on this part of the subject as Beer, whose conclusions (as it also remains, see here in every respect different from those of Bland and Scarpa) for, like the anæsthetic of this pedagogue, he rarely employs the electric plan of treatment, which, according to his principles, is not only inefficient, but harmful, whenever the blindness is attended with determination of blood to the head and eyes, perhaps, an accidental reflexion, or, what is understood by a phlegmatic diathesis. Beer's opinions, respecting the employment of caustic and other means for the cure of anæmia, may be partly collected from the sequel of this article. But more especially from the fuller statement which will be made at a future opportunity.—(See *Glossa Bergei*.) In the mean time, I shall endeavour to offer a general account of the anæmia recommended by Bland, Beer, Richter, Scarpa, Travers, and Lawrence, according to the arrangement of causes adopted by the second of these valuable writers; for I need not repeat, that, wherever the method of cure can be directed against the causes of the disease, it is the most proper and available. The present article will, then, close with some practical observations, chiefly taken from Professor Beer.

In that species of anæmia, which arises from the first class of causes, or those which induce the disease, by means of a preternatural retrograde stagnation of the blood-vessels of the brain or eye, the indication is to lessen the quantity of blood, and the determination of it to the head. For this purpose, the patient may be bled in the arm, temporal artery, or, as is often preferred by foreign surgeons, in the foot. This evacuation is to be repeated as often as seems necessary, and it will be better to begin with taking away from twelve to sixteen ounces. The efficacy of bleeding, in the cure of particular cases of gutta serena, is strongly exemplified by numerous well-authenticated observations. Richter informs us of a woman, who, on leaving off having children, lost her sight; but recovered again by being only once bled in the foot. A spontaneous hemorrhage from the nose and eyelid a young woman, who had been blind for several weeks.—(Amberg, *de Wundt*, l. 3, p. 412.)

That bleeding is sometimes harmful and wrongly practised in anæmic cases, is a fact which admits of no doubt. Mr. Travers particularly refers to one description of cases where the latter does harm; those from cause of active determination of blood to the organ, which is especially common after deep-seated visceral inflammation or disease from over-excitement, by which its vessels have lost their tone; an effort definitely increased by depletion. An interesting case of this kind, is related in the perfect recovery followed a regulated diet, and a course of the blue-pill, with saline aperients.—(Syncope, p. 163.) All cases of direct debility and prope paralysis of the retina (says Mr. Travers) are aggravated by loss of blood, and the great prevailing mistake in the treatment of anæmia, is the indiscriminate diminution of blood.—(Syncope, p. 263.)

When, in addition to general bleeding, relief is also necessary, further may be applied to the temples, or cupping-glasses to the back of the neck, or leeches. Besides bleeding, purgatives, blisters, touching the foot with warm water, see also, above, of the uterus, &c. are frequently proper.

To such cases, the foregoing means that is proceeding

the desired benefit, even when followed up as far as the pulse and strength will allow. Here the restoration of the disease may depend either upon the stoppage of some wasted excretion of blood, or else upon some other cause of the first class. In the first of these cases (says Richter), experience proves, that the disease will sometimes not give way before the normal discharge is re-established. A woman, who, on the anterior aspect of the eye, had lost her sight in consequence of a sudden expression of the mamma, did not recover till nearly six months after the return of the menstrual discharge, notwithstanding the trial of every sort of evacuation. He also tells us of another woman, who had been blind half a year, and did not improve, and in whose interior parts of generation leeches were without effect applied. As often as the leeches were put on (says Richter), the menses in part flowed; and so long as they made this appearance, which was seldom above ten hours, the woman always enjoyed a degree of vision.—(Amberg, *de Wundt*, l. 3, p. 455.)

For the anæmia arising from expression of the mamma, Scarpa recommends leeches to the peduncle, bathing the foot in warm water, and afterward exhibiting an emetic, and saline pills, made of starch and tartaric acid, combined with glyster and moderate anæsthetics. If these means fail in establishing the menstrual discharge, he says, great assistance may be placed in a system of electricity, conducted from the lower sacral plexus, in every direction, and thence especially to the thighs and feet. He expresses no doubt of the want of success at first, as the plan frequently succeeds after a trial of several weeks.

For the anæmia proceeding from the stoppage of an habitual gæstric bleeding from piles, Scarpa recommends leeches and decoctions to the hæmorrhoidal veins, third an emetic, and afterward the same opening pills.—(Observationes in principis Malattie deq. Orchi, cap. 19.)

When the disease does not originate from the stoppage of any natural or habitual discharge of blood, and does not yield to the evacuating plan, Richter thinks the surgeon justified in concluding, that the systemically altered vessels have not regained their proper tone and diameter, and that repeated corroborant remedies, particularly cold water, ought to be employed. In this kind of case, he is an advocate for washing and bathing the whole head with cold water, especially the part about the eyes; a method, he says, which may often be practised after evacuations, with singular and remarkable efficacy.

When the return of sight cannot be brought about in this manner, Richter advises us to try such means as were calculated to stimulate the nerves, and preserve the torpid addition of the optic nerves in particular. Of these last remedies, says he, caustics are the principal and most effectual.

The principle on which Mr. Lawrence directs the treatment, is that of giving a stop to vascular excitement, with the view of preventing the permanent injury of almost strumous, and impaired functions of the retina. Hence he is a warm advocate for the antiphlogistic treatment, in the early stage of anæmia. "But," says he, "if this treatment be not found to remove the change which has been produced in the retina, we must have recourse to surgery, which appears to be as decidedly beneficial in those cases as it is in, or general neural inflammation. The remark which I made respecting the use of surgery in those affections, applies also to the present case; namely, that its good effect usually depends upon the preternatural with which it is employed. The alternative is inefficient; we give it with the view of increasing inflammation in the structure, which is the very seat of disease; that structure is easily changed by the inflammatory process; our only remedy is to push the matter in a decided manner, and if we do so, we shall put a stop to the affection." When the antiphlogistic treatment, and a fair trial of surgery have failed, Mr. Lawrence directs himself with recommending such management as is most conducive to general health; as a residence and frequent exercise in a pure air; plain nutritious diet; mild aperients, with the occasional use of an active purgative; and repose of the affected organ. He mentions also a trial of a tonic, or repeated blisters behind the ears, or at the side of the

ble, which causes modify in the appearance of the body being considerably lacinated, or fissured at the eye, or without larger in particular magenta. The case requires, in particular, general and copious evacuations of blood, and the application of cold vesicles to the eyelids and forehead. An emetic should next be given, and followed a purge of potassa tartaric, or small repeated doses of antiscorbutic tartaric acid. By means of Vesicating and caustic, Scurviness often removed the symptom of soldiers who had lost it in striking forced marches, with very little butting. The Scurviness, usually accompanied by severe anger, in chronic is the more strongly enhanced after bleeding, as the bloodness, their anger, is always attended with a bitter taste in the mouth, tension of the hypochondria, and constant nausea. Most of patients a Scurviness, who become completely blind after being in a violent passion, and which enough has remained the very next day, by means of an emetic, given with the view of inducing severe stress marks of blood disorder in the stomach.

Marjolin's treatment of the improved amaurosis brought on by fever, deep sorrow, great loss of blood, intense study, and those symptoms of the eye on very intense of brilliant objects, consists also in removing all irritation from the stomach, and afterward strengthening the stomach system in general, and the nerves of the eye in particular. In the case arising from fever, the emetic and opening pills are to be given; then bark and opium, and bitters; while the report of the liver amaurosis is to be applied to the eye itself.

When the disorder has been brought on by grief or rage, the stomach and uterus are to be cleared by means of antiscorbutic tartaric acid, and the opening pills; and the choice is to be completed by giving bark and opium; applying the vapour of lighter aromatics to the eyes—aromatics containing, easily digestible food; diverting the patient's mind, and bring it on agreeable scenes, and recommending moderate exercise. The amaurosis from grief is said to require a longer perseverance in such treatment, than the case from sorrow.—(Scurviness Diseases, cap. 12.)

In this country, the emetic practice, which has proved so decidedly efficacious in the continent, has not been attended with much success; Mr. Travers even states, that he does not recollect an instance of decided benefit from it, though he has often tried it fully. He agrees, however, in the indication, as he remarks, that the removal of an irritating or oppressive cause, will often effect a sudden and marked cure, as by clearing the intestinal canal of retained secretions, restoring the digestive functions, or taking away blood where the necessity is indicated. In gastric cases for which emetics have been particularly recommended, he prescribes a long-continued course of the tonic pill, with gentle saline purgatives, and tonic bitters.—(Scurviness, p. 226—228.)

There is also a high authority against the use of emetics, even in the amaurosis from disorder of the gastric organs. When, says he, the subjects have a tendency to be discharged upwards, as indicated by constipated masses and vomiting to vomit, mucus, which never operates without some violence, and is to be most carefully avoided in puerperal individuals, or those who have a violent determination of blood to their heads and eyes, or any compression of the circulation. The caustic here given must be observed, even though sometimes may be often avoided seem advisable; and, according to him, the determination of blood and the state of the system here mentioned, are commonly attendant upon this species of amaurosis. Indeed, notwithstanding the testimony of Welserstein, Richter, and Keemp, in favour of emetics in this case, their position seems, that the violent operation of an emetic frequently converts the sympathetic amaurotic weakness of sight all on a sudden into blindness. Although I myself have seen many have been completely prejudiced against emetics, another obliges me to add, that in this country, their efficacy in the present disease is by no means equal to the representations of Richter and Keemp. When there is less tendency to vomiting, but the case is attended with an oppressive sense of weight about the stomach, frequent eructations, as if arising from rotting eggs, an indurated belly, and loose hypochondria, a gentle aperient course may be tried, especially when the illness have been for some days continued, in which circumstances I have found, that

whenever brisk purgatives are always of the greatest service, when in regard to the general constitution, and the anatomic weakness of sight; the removal of the offensive matter from the alimentary canal being immediately followed by a cessation of the determination of blood generally mentioned. Lastly, when this syndrome originates altogether from the presence of worms in the bowels, common antihelminthics are to be resorted to. In all these cases, says I have, there local treatment is quite inapplicable and very doctored.—(Ibid. Letter vol. 4th August, b. 2. p. 247—251.)

The third species of puerperal amaurosis, is that which arises from retinal inflammation, is of two kinds; in one, the disease is the consequence of a general weakness of the body; in the other, it is the effect of debility, which is confined to the eye itself, and does not extend to the whole constitution.

According to Scurviness, the incomplete amaurosis from general system similarity, requires freshening, general-salt medicines, and long-continued exercise, especially by candle-light; is less a case of total amaurosis, than 2 weeks or eight days a fringed state of the retina, especially of those consisting of the immediate cause of sight. When this complaint is recent, in showing subject, it may be cured or diminished, by stopping the vitreous canal with small repeated doses of stramonium, and then giving tonic cordial remedies. At the same time, the patient must abstain from everything that has a tendency to weaken the nervous system, and, consequently, the eye itself. After stopping the vitreous canal, it is proper to prescribe the decoction of bark with valerian, or the infusion of quinine with the addition of a few drops of sulphuric ether to each dose, with nourishing easily-digestible food. The aromatic spirituous vapours, mentioned in the article Ophthalmia, may then be locally applied; or, if these prove inefficient, the vapour of hyacinth ammonia. The patient must take exercise on foot, horseback, or in a carriage, in a wholesome dry air, in warm weather, and avoid all excess of sun-bathing. He must avoid all thoughts of cure, and remain free from any eyesight-stimulating objects. The impression of vivid light on the retina is always to be moderated by means of the green glasses.—Scurviness, cap. 22.

One case of temporary palsy of the retina from acute catarrhs, mentioned by Mr. Travers, yielded to blennorrhoea, the method, and a gentle salivation excited by calomel joined with opium.—(Scurviness, p. 164.) Another case, brought on by the use of telescope and exercise, gave way to a copious bleeding, brisk purgative with julep and calomel, answers to the torpors, and a course of history.—(Ibid. cap. p. 166.)

Mr. Travers remarks, that the amaurosis from depletion is sometimes mistaken for the opposite case, viz. that from Reticular congestion: this is owing to the continuance of a dilated and insensate pupil, vision, and a deep-seated pain in the head, with occasional vertigo; and its frequent occurrence in a corpulent habit. By a cautious use of venesection says Mr. Travers, it is relieved; by whatever leucorrhoea or stagnation, whether that of menses, it is decidedly aggravated. In this form of amaurosis, vision is further enfeebled by the loss of as much blood as flows from two or three leech bites.—(Scurviness, Act. p. 166.)

When the weakness is confined to the eye, Richter thinks corroborated appropriate more necessary. Bathing the eye with cold water, says he, is one of the most powerful means of strengthening the eye. The patient should lie in cold water a compress, doubled into eight folds, and sufficiently large to cover the whole face and forehead, and this he should keep applied, as long as it is comfortable. Or else he should frequently apply cold water to his eyes and face with his hand, on a piece of rag.

The eye may also be strengthened by repeatedly applying blisters of a sulphuric alkali above the eye, leaving just long enough to excite vesicles. Richter likewise speaks favourably of rubbing the upper eyelid, several times a day, with a mixture of the tincture of hyacinth ammonia and spiritus myrtilli.—Antiquary der Wundarzt, b. 2. p. 452.

When no probable cause whatsoever can be assigned for the disease, the surgeon is justified in employing such remedies, as have been proved by experience to be sometimes capable of relieving the affection, although upon what principle is utterly unknown.—(See Gouta Serena.) To this article I would refer the reader

before he makes up his mind about any extended period of treatment, because he will have had many cathartics and emetics given by him, respecting the remedies for amauirosis in general. To his remarks, I have also inserted some others, on the same topic, as appeared to me interesting.

Causes common to

This species of the disorder, of which I have met with but two days, nearly unknown to complete blindness; it occurs chiefly in very old persons, and it is perhaps the affection in which some writers have given the misleading name of "atrophic amauirosis." Sometimes, however, this kind of amauirosis takes place in young persons and children; and one circumstance that so rarely presents itself in the preceding is, that it always takes place rather in thin, emaciated, old, gray-headed subjects, usually in the case of hereditary scurvy, in whom consequently the weakness of organs rather is carried on to senility, or else in young subjects, who are scurvyish, and disposed to consumption, hectic affections, emaciated children, and so in a catalogue of various injuries of the eye. While this amauirosis is not perfectly formed, the iris retains its maturity, and the pupil is neither preternaturally dilated nor contracted; but when once the patient is quite bereft of vision, the muscles of the eye are slow, and the pupil larger than in a healthy eye in an equal degree of light. At the bottom of the eye, very far behind the pupil, a excessive pale-gray, lardaceous-yellowish, or variegated reddish opacity is developed. By this the sight is not really weakened, but rendered quite confused, since all objects, but especially smallish ones, appear to be confounded together, particularly when the patient tries to inspect closely any determinate body. The duration of the disease advances, eye brighter and more visible in the bottom of the eye, the pupil is the color of the iris; a strong very conspicuous, dark-eyed person; and when once the amauirosis is complete, so that no susceptibility of the increment of light is left, then, upon an attentive examination of the eye, one can not merely perceive, in the troubled deeper part of the eye, a very slender vascular streak, which merely consists of the ordinary ramifications of the central artery and vein, which are more visible at the pale-colored bottom of the eye. In a half-darkened place, such an eye presents a shining yellowish or reddish appearance, but only in certain positions of the eyeball, such, in this respect, is somewhat similar to the eye of a cat, wherein I have chosen to term the complex of all these transitions. The disorder is also accompanied with any other essential morbid appearance, except the dilation of vision or complete blindness.—*Lieber von dem August 1. 2, p. 506.* Beer, in *Fig. 1, tab. 4* of his second vol., has given three rather agreeable representations of this very remarkable species of amauirosis. The difference in the appearance at the bottom of the eye, in this case, from those presented in the early stage of fluxus lachrymosus of that organ, will be best understood by referring to the article Fluxus Lachrymosus. On this point, however, I may here briefly state, that in the cat-eye amauirosis there is no projection, but, on the contrary, a notable depression in the axis of vision. Cat-eye amauirosis may be known from twilight amauirosis, by the opacity being more deeply seated, and having a shining, partly crystalline.—*See Journ. of Foreign Med. Vet. 3, p. 125.*

Beer observed that the process of this species of amauirosis is so slow, that whenever it afflicts upon the subject can be removed with impunity. After what has been said in the foregoing paragraph is considered, about the particular individuals who are likely to be afflicted, and the change of the eye to a pale color, as a common symptom of this case, a suspicion may be entertained that a deficiency of the parietal nutrition, and of the tension of the iris, in consequence of the stoppage of the secretion, may be the cause of the disease. Beer justly remarks that much might be learned, on this point from the dissection of eyes thus affected; but he has never met with the opportunity.

The prognosis cannot but be very unfavorable; for, as the amauirosis is general of course, he almost never will receive credit to be adopted for their removal. It is fortunate, however, that this amauirosis rarely attains the highest degree, but always remains in the form of a more or less considerable misty opacity.

Just as little is yet known respecting any well-regu-

lated mode of treatment; for the disease may sometimes be kept quiet, putting more by the careful employment of such general measures, regimens, and diet, as are calculated to improve the health. However, in the most frequently managed cases, few ever know a step made towards the removal of the disease.—(*Lieber von dem August 1. 2, p. 487, 498.*)

Amauirosis produced by fluxus, certain periods of lead in particular constitutions, or the poison of lead.

The reality of the first alleged cause is sometimes doubted in this country. The following treatment is recommended by them. In the first stage he advises gentle mercurial cathartics. When profuse menses, a few ounces of blood may be taken away by venesection or leeches applied behind the ears; when after bleeding a determination of substance towards the eye still continues in full action, or there is any tendency to inflammation. The same topical bleeding without venesection, but with leeches put on, containing such or mild, is proper when no general plethora exists; and merely a determination of blood to the head and eye and some suppuration of the circulation prevail. Frequently, leeches put on to the supra-orbital vein has excellent effects; and externally, positions composed of head-ouch and vinegar, or fomentations containing opium, are the means which Beer has found most successful in the first stage of this form of amauirosis.

As in the first stage, a moderate antiphlogistic general or local treatment is the only one which can be adopted, and which in urgent cases may yet avert the patient from blindness, so in the second stage no internal and external employment of lead stimulants is of great service; for example, mercury combined with opium inwardly, lotions to the eyeballs, and the exposure of ether to the eye. The amauirosis produced altogether by the poison of lead, and complicated with headache and illness, will require, in addition to the foregoing means, such remedies as are known to be of service in these latter disorders.—*Beer, Lieber von dem August 1. 2, p. 498—502.*

Systematic amauirosis in individuals affected with Acute, Apoplectic, epileptic, and convulsive.

This amauirosis is nearly permanent, and usually succeeds as soon as the apoplectic, epileptic, or convulsive attack is over. However, the complaint may begin at two periods, viz. either during such an attack, or (what is more uncommon) afterward, and it never loses its symptomatic character. The pupil always remains perfectly clear, and of a shining blackness, even when the disease has attained entire blindness; but a slight dull pain in the forehead, especially about the eyebrows, constantly pressing and accompanying the blindness, generally lasts a great while after the amauirosis has completely subsided.

Besides the foregoing general symptoms, the following characteristic appearances present themselves in apoplectic and apoplectic patients, who suffer frequent attacks of violent spasms. The pupil is much dilated, and the iris, which is translucent, seems evidently to project in a convexity forwards, when the eye is inspected sideways; consequently, the anterior chamber is flattened. The eye itself does not seem freely in the socket, the patient experiencing an itching, and sometimes a truly painful sensation, as if the eyeball were loosely connected (Ophthalmodynia). Every attempt which the patient himself makes to move the eye, or the surgeon to push it out of the position which it has assumed, is ineffectual and extremely painful. The eyelids are either partially shut, or incapable of being shut at all; the sight is very weak, but seldom quite extinguished; and at the termination of each attack vision returns, though every patient knows it more and more debilitated, until at length the spasmodic attacks of blindness frequently occurring, and lasting a long while, it is entirely lost. But when the disease has acquired its utmost degree, the eye always will retain the power of discerning the light, and a sudden lapsus that vision is attended by the first or second attack. It is different with respect to the symptomatic phenomena of this amauirosis, in hysterical or hypochondriacal patients, especially when they are afflicted with spasms, before, during, or after which the impairment of sight originates; for though the pupil may continue quite clear, it cannot escape the notice of an attentive observer, that, together with a

med of diminished diameter, there exists a peculiar method of the iris, a constant flattening of it between expansion and contraction, technically called *hypoplasia pupillæ*. This convulsive state of the iris is usually accompanied with a similar affection of the eyelids, namely, with an involuntary blinking, sometimes, and not infrequently with an involuntary pendulous falling of the eyelid (ptosis). In these patients the amaurosis, being of sight hardly ever present, appears to complete blindness, but, taken correctly to mean as a weakness of vision, characterized during the rest of life by numerous fluctuations of the eyeball, directed to light, and frequent sensations as if there were shining very objects before the eyes.

This case of sympathetic amaurosis is characterized by an untroubled, but very expanded pupil; considerable dilatation of the margin of the iris; a dilated state of the pupil, even under the stimulus of the strongest light, and tremulous motion of the eyeball, which continues during life, after the epilepsy and amaurosis are cured; and the case is further characterized by myopia, which rarely increases to complete blindness.

According to Beer, the amaurosis connected with convulsions is most frequent in children. The first and most constant symptoms of this incomplete or complete amaurosis consists in an extremely violent convulsive motion of the eyeball, especially upwards, not infrequently attended with the most violent convulsive motions of the eyelids. The pupil is excessively dilated, and scarcely the least movement of the iris is distinguishable on exposing the eye to the strongest light. When the general twitchings subside, and only an spasmodic weakness of sight is left, strabismus occurs in both eyes in various directions, though the eyes very seldom deviate from the axis of vision in the direction towards the inner canthus. When the general convulsions happen frequently, and are violent and of long duration, the amaurotic weakness of sight usually changes into perfect blindness, in which the pupil, though it be regularly dilated, and of a shining brightness, is greatly expanded, and the eyes constantly retain their fixed position and position also motion.

With respect to the prognosis, it is observed by Beer, that even when merely an amaurotic weakness remains, the prognosis is always serious, but it is naturally still more unfavorable, when the blindness is complete, and when the loss of sight has suddenly resulted after violent spasmodic, epileptic, or convulsive attacks, without such attacks themselves ever returning. Under these circumstances, Beer has not hitherto seen more than two instances of such blindness partially cured. Especially some lapses of recovery may be experienced, when the amaurosis, or even complete amaurosis, begins with these attacks, but always terminates with them, without leaving any serious impairment of vision. On the contrary, it is a very bad sign, and only in regard to the removal of the hyperplastic amaurosis, but likewise in the cure of the organic disease, when the amaurosis gradually precedes these attacks, and lasts a considerable time after their cessation. As yet, Beer says, he has not known any such patients cured, either of their spasms, epilepsy, or convulsions, much less of their blindness; on the contrary, after three or four attacks, perhaps numerous seizures, and some of the patients die in one of these paroxysms.

As this amaurosis is merely a symptomatic effect of the above general diseases, its removal must entirely depend upon the success with which their treatment is conducted. Were the hyperplastic process, however, after the cure of the organic disease, the vision could be restored after time by an artificial mode of treatment, and ascertain what good could be effected with strabismic and tonic medication. — Beer, *Kleinewassersdorfs Archiv*, 1, 2, p. 308—410.

Radiating amaurosis.

According to Beer, radiating amaurosis is not very uncommon, and is as plainly marked by certain symptoms, that it scarce will be mistaken; namely, a perfectly white pupil, various in the fixed state without contraction and dilatation, the iris seeming to be nearly transparent; the eyes when from the slightest causes, and especially being moved or less inclined to light; the case is invariably attended with wandering, irritating pains, sometimes affecting the eyelid itself, sometimes the vicinity of the eye, and in other instances, the teeth or neck. After these two eyes are affected to-

gether, which is not regularly the case, a crust of the eye, which cannot be called actual matting, may be removed, and frequently the surface of the crystal is chiefly obstructed only in one direction, though sometimes a true strabismus of the eyes exists (Beer). In nearly every instance there is considerable weakness of the lower parts of the upper eyelid, and not unfrequently, a complete *blepharoptosis*, but total blindness is seldom produced.

According to Beer, this amaurosis, which is to be considered an organic affection, often arises from keeping the head long exposed to the air and is chiefly met with in individuals who, while suffering profusely from the scalp and hair in warm weather, have taken off their hats, and remained with their heads a long while uncovered. As, however, in warm weather the proximity of persons exposed themselves to sun-bath, and few are attended by persons, I infer that sweating may be requisite for the production of the disease.

Under certain circumstances the prognosis is by no means unfavorable, and Beer has succeeded in effecting a perfect cure, when the amaurosis was not completely fixed, and not of very long standing, the patient had no tendency to gout, and when during the treatment every thing likely to bring on an attack of that disease was avoided.

The treatment consists not simply of local matter, which indeed are always needed, but likewise of general measures. With regard to the latter, Beer assumes that valuable experience has observed less of the prognosis which ought to be given to the extent of radiation joined with matting, and given alternately with the compound powder of quercus bark; which powder, as soon as the wandering pains about the eye and eyebrows begin to be milder, and more fixed to the part, are to be succeeded by the extract of nuxtina, antiscorbutic preparations, and fumes of sulphur. Externally, the most powerful opening ointment are not to be omitted, especially flinties applied successively behind the ears, to the temples, and externally; and as soon as the pain has completely subsided in these last parts, and as perhaps more concentrated in the eye, flinties are to be made on the eyelids with balsam, containing at first a stibiac quantity of aqua, and afterward of the sulphuric acid. At length, when the pain is and about the eye is greatly subdued, but some degree of amaurotic weakness of sight is left, flinties with nuxtina and a small proportion of tartaric lime and tartaric acid will be found exceedingly beneficial. Afterward, when a considerable time has elapsed without the restoration of the slightest sensitive part in the eye, its opacity, or the loss, but the amount is not probably established by perseverance in the above general and local treatment, and especially when the patient is formed of the larger of one or more of the upper eyelids continue as when happens, galvanism may be tried, with the current elsewhere provided. — (See Kleinewassersdorfs Archiv.) And in the most desperate cases, Beer advises of making an incision in the depression between the angle of the jaw and the maxillary process, and keeping it open for a fortnight, after the recovery almost complete. — (Lieberkühns Archiv, 1, 2, p. 340—350.)

Tranquil amaurosis.

Beer applies the epithet "tranquil" to such cases of amaurosis as are the consequence of a considerable wound of the eye (such as wounding parts, or the globe). Here, consequently, is first changed the strabismus produced by the irritation and contraction of the lachrymal and the frontal nerves, from a constant into the tremulous. Secondly, Beer reduces the considerable swelling from external violence directed in such a degree against the upper or lower side of the globe, that the retina is torn and many of the essential vessels portions of the eye forced out of their natural situations. Thirdly, Beer includes every weakness of sight or perfect blindness, which is the result of such injuries of the eyeball, though not attended to the cause, as the effect, viz., to lacerate lacerate eyes and to pierce it. For the prognosis and treatment of all these cases, he refers to his observations upon strabismus. Not does he choose here to treat of the perfectly congenital amaurosis, which is a direct consequence of a deep-seated, because it never happens unperceived by a violent general inflammation of the eyeball, and therefore is to be regarded as an effect both of the injury and the action.

man together; but which, like the sympathetic anisocoria, following common and passive external spasm, may be easily known by the total insensibility to light, and the evident changes in the contour and shape of the eye; and is quite as treatable as the other anisocoria in which we have alluded to.—(Lect. von den Augen, 1. 2, p. 541.)

Grey amaurosis.

According to Mr. Travers, good attacks of the eye through the medium of the stomach. Vomiting occurs with pain in that organ, on the subsidence of an inflammation in the circulation, and is succeeded by violent pain in the head. The loss of sight is sudden, is sudden and permanent.—(Synopsis, &c., p. 182.) The grey amaurosis described by him, is, perhaps, badly named; at all events, there are some circumstances in its history which must cross the idea of the subject. Grey amaurosis, he says, has two forms. The first is characterized by a very considerable distention and angular displacement of the pupillary edge of the cornea towards the centre; a constantly increasing slowness in the movement of the iris, and final insensibility of this organ; an actual change of colour in both the circles; a dull, glossy blackness of the pupil, and a certain taint in the latter of the serum; an alternate appearance of the grey and black cloudy substance described in the account of the general symptoms of amaurosis, which effect lasts while the patient is not totally blind. This disorder is further indicated by a floating, wandering, itching, yet not very severe pain, all about the vicinity of the eye; a manifest tendency to a various enlargement of the blood-vessels of the conjunctiva and sclerotic; a transient metamorphosis of sight after meals, or any condensed nourishment; or, sometimes, a considerable temporary decrease of heat of the species of air which breathes the patient; the transitory cure remission of the disease, for which several years are usually required; and finally, by the nature of the patient's constitution. For, in general, this amaurosis if he is a scrofulous man, always attacks both eyes at once, and is confined to elderly and very imbecile, slender, weak, delicate figures, who either have suffered from scrofula in their childhood, or from hereditary or chronic diseases at a later period of their lives; who are not yet far advanced in years; and whose tissues have never been very life-giving though profuse.

It is remarked by Beer, that although the second form of grey amaurosis makes no attack upon males as well as females, the latter, on the whole, are more frequently affected, particularly about the period when the system cures. This amaurosis, which is seldom fatal quickly, but is, at all events, in months, but mostly requires years for its production, begins with cloudy, indistinct vision; an appearance of filigree colours before the eyes; and a peculiar squinting, as if persons were travelling over the sky shaded eye. The pupil becomes incessantly dilated, and presents a rich greenish-gray colour, which, however, is easily distinguished from the colour seen behind the pupil in the anisocoric eye, and gradually deposits upon some fibres in the vitreous humor (phlegma). Also the iris, the pupillary edge of which is drawn towards both angles of the eye, so in the first form of the disease, transforms an obvious change of colour, first at its best circle, which becomes of an exceedingly dark line, and then in its greater parts. The alteration of colour from redness of certainly proceeds from a general varicose state of the blood-vessels of the eye, which affection daily augments, and is attended with increased pain in the organ and surrounding parts; it even in the whole head, or one side of it, whether the blindness attack one or both eyes together. This violent pain, however, which is such as often to distract the patient, is transient and irregular, being immediately aggravated by every violent mental emotion, whether of the exulting or depressing kind, every sudden and considerable change of temperature, every quick accession of any cold weather, or when the patient stays only for a short time over a very heated fireplace, from hot bath, or even with flannel, or he has been eating any indigestible food. These attacks of pain subside without any medical assistance, at the dry, warm season of the year, and in a mood, but too late, climate are often kept off for several years. Upon every

such attack the glaucous becomes more evident, the pupil larger and more angular, and the eyelids perceptibly weaker. At length, during one of these painful exacerbations, vision is completely abolished, and the least sensibility to light remaining; and the pupillary edge of the iris, together with the base, circle of the same organ, then entirely disappears, being inverted towards the iris. The circumference also gets so much swollen, that the cornea acquires a watery, grayish color, and in length the black substance of the iris may be perceived at various points, particularly about the place where the fibres of the arteries are affixed. Afterward the pupil, or what may be more properly called the glaucous circle, is gradually developed, and the eye then gradually returns under the most violent attacks of pain. The light which the patient always thinks he sees, but which, according to him, is produced of a reddish or brown color in the interior of the eye, like grayish, keeps up the hope of recovery; but as insensibility of this luminous appearance ceases as soon as the eye begins to mend. The first degree of grey amaurosis readily changes to the second, especially in persons who are getting into years, or are over the period of life when inflammation subsides.

According to Beer, the apothecary's magnifying glass is no medicine which is adequate to the cure of the first form of this amaurosis. A good change of the whole constitution, would be requisite, are success could be expected, and such change it is not in the power of physic to accomplish. In one single example Beer succeeded in checking the disease, by persuading the patient to observe a strict regimen, and a grain of medicine being given; but the patient still remains weak-sighted, though various medicines have lately been tried.

With respect to the treatment of the second form of grey amaurosis, Beer observes that it should be like that of grey tritis. In particular, attention must be paid to the effects of pain, and patients must be advised. The patient should be upon further beds, and especially feather pillows, but only employ articles of this kind which are stuffed with horse-hair. Neither must he expose himself to an atmosphere which is at the same time both cold and damp; and if he cannot altogether take care of himself in this respect, or if events let him keep his head and feet warm and dry; when everything which tends to impede the functions of the skin; and avoid pork meat, every thing cooked with sage, lard, and oil and salt dishes, like hennings. With what are usually considered as good medicines, the practitioners should act very circumspectly; and, as in grey tritis, he should pay close attention to the state of the constitution, rather seeking to afford relief by means of a well-regulated diet, than by the employment of much physic.

Of the amaurosis occasioned by the sudden rarefaction of the vitreous humor, and of all others of this kind.

When the amaurosis assumes its ordinary form, Beer has not yet been able to decide if it is any particular characteristic symptoms by which it can be effectually distinguished from the second form of grey amaurosis, excepting, first, that it originates and increases very suddenly, while the true anisocoric amaurosis is a long time, and the first pain several years, is forming. Secondly, that at its commencement it is never attended with violent pain in the eyes or head. Hence, the diagnosis will depend very materially upon a correct recognition of circumstances. But, according to Beer, there are some cases in which, besides the complete blindness, unattended with the slightest power of perceiving light, there is no characteristic symptoms, but extraordinary enlargement of the pupil, total insensibility of the iris, and an insensate projection of the iris.

Regarding the cause of this amaurosis, Beer says that he has nothing important to offer. He owns that, after the sudden rarefaction of the vitreous humor, and of all kinds of the lens, an amaurotic blindness does not always ensue; and he believes that the reason why this does not ensue in other organs, sometimes the brain, the lungs, or the testis, &c., may probably depend upon the fact that organs depending to be most predisposed to disease. There the disorganizing matter will not require so long to take hold of them that such a mode of accounting for things is entirely hypothetical.

and destitute of proof. It is indeed so correct in a series of explanations that it admits of being extended to all diseases without exception. It seems to be reasonable, the progress is very important, and in many cases highly instructive; that, because an organic part, namely the optic nerve, is directly affected, which, by the operation of external and internal causes, is even rendered unfit for the performance of its function. Secondly, because in the majority of examples important changes immediately take place in the organization of the whole eye, which are particularly difficult of removal when the nervous system is affected. Thirdly, because it is impossible to know whether morbid changes may not usually arise in the retina as a consequence of the optic nerve.

In the treatment, Beer, who places great reliance upon the above statement of causes, is an advocate for suppressing as quickly as possible the original disease; and if that cannot be done, he thinks some artificial disease should be formed in lieu of it. For these purposes, he often employs blisters and friction with mercurial ointment. The treatment, where mercurials happen to follow the cure of itch, seems very objectionable, as it consists in inoculating the part with virus, which is quite infected, as if it were not more favorable to remove than that like perpetually associated with the other disease; the professor's theory being transformed by the circumstances under which the patient whose sight is restored by this exposure could ever venture to have a sore skin again without the risk of a fresh attack upon his eye. But it seems, from Beer's account, that the patient's suffering himself by the mercurial can always cure his eye; for, says he, when this method fails, there is still rational treatment should be tried.

When amaurosis follows the healing of old sores, Beer recommends the formation of fresh sores, by applying to the cornea various caustic compounds, and the use of soda; and if the new vessels cannot be made to discharge properly, he proposes the application of issues to the sides of the face, and, in urgent cases, to the thighs. These plans are to be aided by such medicines as are especially good for the skin, the artemisia, especially the sulphur artemisia effluvia. Beer also speaks favorably of sulphur baths; and in cases complicated with debility, aromatic wines, particularly the odorous aromatics and bark.—(See Lehrbuch des Augenheils, b. 2, p. 526—533.)

Of the sympathetic anisocoria in being in nature, from suppression of the secretion of milk.

This case is set down by Beer as one of the most interesting varieties of anisocoria. It comes on rapidly after sudden stoppage of the secretion and excretion of the milk, with violent inflammation, concentrated about the forehead and eyebrows; troublesome lacrimation appears; an insupportable distention of the pupil; and scarcely any perceptible irregularity in the pupillary edge of the iris, which is quite motionless, somewhat shagreened in color, and veined. The disease is also accompanied with great aversion to light; a palpable tumescence of all the blood-vessels of the conjunctiva; a slight turbidity of the transparent media of the eye; and, at last, with a more weakness of sight, which, in the end, suddenly changes into complete anisocoria. The breast, when before the attack once full of milk, are now empty, and hang down like bags, but are quite free from pain.

From the few cases which Beer had seen, he inferred, that the progress is always unfavorable when the mammae are engorged, and particularly when there is a marked distended change in the transparent parts of the eye; for, in the latter case, he has known patients remain perfectly blind, though the secretion of milk had been most successfully and expeditiously re-established. In one instance, the remedy applied to the breast, instead of re-establishing the secretion of milk, excited in the part a painful inflammation and abscess, dying: While the weakness of sight subsided, though it was very considerable.

In considering these analogous cases of anisocoria, enough has already been said, concerning the first and most important indication, namely, the re-establishment of the action which is obstructed, and here the only question is, about the manner in which that object can be most expeditiously and safely effected. For, says Beer, it should be constantly remembered, that the pro-

vision of a complete anisocoria blindness essentially depends, not only upon the removal of the secretion from the breasts, but upon this change being made without delay. The remedies which Beer has found most effectual for this purpose are warm poultices applied to the breasts, and at first composed of simple emollients, and afterward of more stimulating ingredients, such as linseed, chamomile flowers, &c. When the breasts have more of a leucophlegmatic appearance, then that indication of a fulness of the mammae passed, and disposition to a removal of the milk secretion, Beer anoints them plentifully with aromatic unguent, and applies them alternately with well-washed linen, full of dry aromatic plants, and sprinkled with camphor. These last unguents are very useful, at night, or when the patient is asleep, and from warm poultices cannot be put so effectually often. In the daytime, the breasts should be frequently and gently rubbed with warm liniments, medicated with oil of rose and yucca. This plan is to be followed up until the secretion and excretion of milk are restored, and the anisocoria subsides. When the secretion either cannot be restored by the foregoing means, or the sight does not return with the re-established secretion, internal remedies must be tried, especially arsenic, joined with calomel and camphor. Issues or sinuses should also be formed, and kept open for a considerable time.—(Lehrb. von dem Augenh. b. 2, p. 532—533.)

Of the sympathetically anisocoria from morbid changes, either in the optic nerve and other channels, or in the brain of the patient, or the brain itself.

Beer says, a very considerable number of cases of this form of anisocoria, which have often lasted long years, have existed than, as it were, yet only to know it at once, but so obscure the exact symptoms.—1st. Its duration is constantly very slow, and it is all cases the patient is not very completely deprived of vision, but, for more or less time, previously to its death, rendered quite incapable of distinguishing light. 2dly. A violent peculiar symptom of this anisocoria consists in marked changes in the structure of the eye, which are at first almost perceptible, and increase very slowly. 3dly. The anisocoria either originates during an attack of violent headache, which continues almost uninterruptedly until death, or the headache does not come on until complete blindness has taken place; or the patient may have no pain whatever either in his eye or head. 4thly. In the progress of this anisocoria, objects invariably seem to the patient to be perceived, distorted, &c.

Symptoms when the disease proceeds from disease of the optic nerves or their sheaths.

This case comes on slowly, and rarely attacks both eyes together. It always commences with a black cloud, which grows more and more dense, and with a headache, increasing prostration and disfigurement of every eye, without the least painful sensation in the eye or head. The patient usually complains of a slight sensation of dull pressure in the bottom of the orbit, as if the eyeball were about to be forced from its socket, or slight displacement, however, there is not the usual anisocoria. In the very beginning of the disease, the pupil is slightly considerably dilated, and the pupillary vessels of the iris become very prominent on several points, the pupil sometimes representing an irregular position or hexagon. By degrees, though very slowly, a pronounced change of the various lacinated vessels, and afterward of the lens itself; the only species of glaucoma, which Beer has ever seen quite inviolated with a various affection of the blood-vessels of the eye. At last, the globe of the eye becomes perceptibly smaller than natural; but a complete atrophy does not ensue.

Symptoms when the case proceeds from disease of the skull or brain.

In this form of anisocoria, which usually attacks both eyes together, or at least one very soon after the other, the blindness then commences very slowly, with appearances as if every object looked at were perceived or distorted. However, there is no black cloud, but rather an obscurity or confusion of every object. The disease in this stage is slow accompanied with frequent sickness, ugly nervous spectra, and, for the most part,

with aversion to light, unconsciously early closure of the iris, a contracted pupil, angles in the upper and lower portions of the pupillary margin of the iris; no evident transgression of the blood-vessels of the eye, gradually augmenting with more violent localities this actual atrophy of the iris; frequent convulsive spasms of the eyes and eyelids, and strabismus of one or both eyes, making a great deviation of one or both of these organs from its normal position. Under these symptoms, vision is altogether entirely abolished, and the headache, though subject to remissions, grows so violent, extending back to the spine, that the patient is often nearly frantic, and, indeed, after a time, a destruction of the cerebral sensorium happens, followed by that of the medullary function. The first of the sensorial sensorium strikes as last is always the hearing, which ordinary is mind follows by loss of the smell, or taste, or both these senses together; and then the memory and other intellectual powers decline. In this stage of the disease, the eyeball too unfortunately protrudes from the orbit, a pathological symptom, to which their attention given importance, because it is an infallible criterion of a diseased state of the tissue of the orbit, of the parts which invest this cavity, and of the optic nerve and their roots, in the same manner. In such cases, complete blindness usually follows, and this sometimes in its most violent form, when the patient happens to be first carried off by paralytic symptoms; life, under these circumstances, never lasting any considerable time.

As far as our external senses can discover, the cause of both these forms of amaurosis, as the title of this section specifies, lies in certain morbid-changes in the structure of the optic nerve and its investments, or in diseased affections of the houses of the contents, the dark matter, and the brain. But how these changes arise, is not so easy of explanation. The several changes in the structures above mentioned, which have been described, accompanied by atrophy, caused in a real isolation of the optic nerve, and an isolation of them as their sheaths, while within the skull these are colored, gray, very much diminished curves presented to view of medullary structure even as far as their origin from the brain. On the contrary, the white substance presented externally its natural appearance. The retina seemed to have lost its pigmy matter, was bright, not easily torn, and appeared to contain but of a vascular appearance. In one example, although both eyes had been completely deprived of sight together, there found only the retina and optic nerve of the left side in this state of atrophy as far beyond as the point of union in the optic nerve. On the other hand, the same nerve of the right eye was hard, without being in the least divided, and was closely adherent to its external coverings. Apparently to their destruction, looking at all anatomical in order there could be discerned, that a very sharp, strong scraped was required for its removal, though in color and shape it was perfectly natural. On this side, also, the pia mater choroid was entirely wanting. In three associated patients of this kind, there found hyaline between the coverings of the optic nerve, and where such hyaline lay, the medullary matter seemed to have been displaced by their pressure. With the utmost care, he could not trace the degenerative changes.

Now also found in the optic nerve a large hyaline, which had produced atrophy.—(Obs. Anat. Harv. Obs. 2.) In Mr. Munk's case, there is a projection of the optic nerve of an anastomotic eye, where a tumor of considerable bulk has arisen from the base of the brain.—See Woodbury's Essay on the Medullary Anatomy of the Human Eye, vol. 2, p. 127. In that work are several examples of various other morbid changes of the optic nerve, especially calcareous concretions within it, the presence of a bony matrix, gray fluid in the diseased material, instead of gray, a swelling of the nerve, &c.

To the present description of cases, they refer the instance recorded by Rudol. Ophth. Period. Obs. 10, p. 173, in which a calcareous tumor was found between the lamellae of Hyack and the vitreous humor. According to him, there is preserved in the specimen and anatomical processes of the general hospital at Vienna, an eye, diseased with a smaller calcareous mass, without the exposure of the lens being at all affected. Examples, in which the atrophic changes

arise from atrophy in the brain, are reported by Hallerius (Observations Hist. 7, by Pylagius (Med. Aug. 2, p. 110, by Goussier (Mémoires de l'Acad. Turin. Obs. 1, p. 212, Schenckius (Eph. Nat. 1, p. 11), and Mr. Turner (Synopsis, p. 143). The latter author has recorded an instance in which a firm lamellar tumor, of the kind of a garden hose, situated on the same side as the blindness, comprehended the optic globe and nerve at its origin from it.—(Synopsis, p. 151.) I have seen a case of atrophy, in which a tumor as large as a building-sized apple was found in the external lobe of the brain, divided with pressure of the eye, and vast destruction of the brain. Mr. Turner has been mistaken by a medullary tumor of the brain. A case, occasioned by division of the lamellae, is related by Villeneuve (Journ. de Médecine, 1811, Fév. p. 19); another, of a tumor of the lamellae on the same side as the blindness, is recorded by Feil (Med. Constat. vol. 1, No. 4), and other instances in various parts of the brain are described in Ephes. Nat. Cur. Dec. 2, Ann. 6, and in Obs. 253; De Harv. Ratio Medendi, T. 4, p. 151; Ann. des Sciences, 1807; Munk's Winkler, 2, No. 13; Taber, Obs. 1, p. 108; Thomson, Anatom. p. 100, by 100, &c. On this part of the subject, I beg leave to refer also particularly to my friend Mr. Woodbury's valuable Essay on the Medullary Anatomy of the Human Eye, vol. 2, p. 174, &c.

The several alterations of the house of the cavity of the skull mostly happen at its basis, and not only may cause take pain, but still more frequently evidence of various forms, which are sometimes so small that they are first detected by the bone giving the feel of a rough granule. At the same time they are so slight, that if the finger be passed rapidly over them, it will be scarcely felt. In these cases the house of the cavity of the skull undergoes several extremely thin; the diploe is almost entirely wanting, and the portions of the orbit are preternaturally augmented, and in some places ruptured. One specimen of a lady's skull who had been completely blind, and for some weeks previously to her death insensible, in which instance scarcely any part of the cavity of the skull could be usefully reached without risk of scratching the fingers with spines. Once in an anastomotic boy, who for a short time before his death was so insane that he used to devour his own excrements, there found at the side of the sella turcica a long considerable spine, which passed directly through the optic nerves at the place of their decussation. A case of atrophy produced by a spasm of bone is given, the opposite side of the brain is related by Anderson.—See Trans. of the Society of Edinb. vol. 2. Sometimes the atrophic bone has been found carious (Baltimore, Philadelphia, No. 7); sometimes other parts of the cranium.—(Munk's Winkler, 2, No. 6; Schenckius, Vermischte Schrift, 2, p. 12.) Nor is it uncommon to find the medullary substance of the brain hard as soft as pig, while the external substance is full of blood-vessels, and unusually firm, the decussation being hardly distinguishable.

Many of the causes of amaurosis are of such a nature as to render the disease totally incurable. Of this description is hyperæsthesia, in which the structure of the retina and optic nerve is changed in a remarkable manner, the whole cavity of the eyeball becoming filled with a substance resembling medullary matter, and the optic nerve changed in its form, color, and structure.—See Woodbury's Essay on the Medullary Anatomy of the Human Eye, vol. 2, p. 130; See Lond. 1815.

On the authority of Kirker, one case is given, record, where the sense of sensation depended upon an atrophy of the central cavity of the brain.—(Phil. Neurographia, vol. 2, p. 122.)

In another instance the vitreous humor, which is naturally a yellow gel, near the center of the retina, was found black.—Munk de in Specul. Med. d'Observation, 1818.

Binocular, it has Schenckius (Anatomia, 18, 1, sec. 18, describes various cases which were quite incurable; after both the blindfold in one instance was found to be accompanied by an encysted hyaline, weighing fourteen drachms, situated in the substance of the vitreous, and pressing on the optic nerves near their origin. In the second, the hardness was produced by a cyst containing water and lodged on the optic nerves

Where they arise. In the third, it arose from a variety of the *op. thalam.* and a *conspicuous* aberration in the form of the optic *thalamus*. In a fourth, the cause of the disease was a malformation of the optic *thalamus* themselves. In some of the instances in which an aberrant aberration was discovered in the optic *thalamus*, the Mr. Ware conjectured that a dilatation of the inferior portion of the *cornea* anteriorly may be the cause of the affection. The *circulus arteriosus* is an arterial circle, surrounding the optic *thalamus*, formed by the carotid arteries on each side, branches passing from them to meet each other before, and other branches passing backwards to meet branches from the basilar artery behind. The anterior part of this *circulus arteriosus* lies directly over, and is in contact with, the optic *thalamus*, and just in the same way as the anterior branches of the optic *thalamus*, the posterior may lie over the *truncus cerebri* below. Hence Mr. Ware attempted to infer the aneurysm itself, and the paralytic affection of the eyelids and muscles of the eye, sometimes attendant on the complaint, to a dilatation of the anterior and posterior branches of the *circulus arteriosus*. The frequently distorted state of the trunk or small branches of the *cornea*, anterior to the side of the optic *thalamus* is noticed by Dr. Baillie in his useful work on *Morbid Anomies*, and he says, the same sort of dilated structure is also found in the basillary artery and its branches.— See Ware's *Chir. Obs.* on the Eye.

In 1920, M. Magendie related to the French Academy of Sciences various facts emphasizing the remarkable influence of the fifth nerve on all the senses, and with respect to the sense of sight, he finds that the action of the eyeball and optic nerve cease immediately they are completely deprived of the influence of these nerves. Thus a state of the eye is produced that has the grossest analogy to myopia. Indeed, when the fifth nerve is divided in an animal, it is instantly bereft of sight on the side on which the nerve has been cut, notwithstanding the eye retains in the normal all the physical conditions necessary for vision. It is not to be supposed, however, that the fifth nerve performs the function usually referred to the optic nerve. To perceive the light, and to see, as Magendie remarks, are, approximately speaking, two different things. An animal whose fifth nerve has been divided does not see, neither is it conscious of the brightness of the strongest artificial light; yet it demonstrably perceives the impression of the rays of the sun when they fall directly on the eye. Hence a heating, warm condition of the optic nerve on the one part, and of the fifth nerve on the other, is essential to perfect vision; and M. Magendie therefore deems it highly probable that there are two kinds of myopia, one depending on a particular alteration of the optic nerve and retina, the other an disease of the fifth nerve, and also defect of its influence on the organ of vision. These deductions led him to make trial of a combination of acupuncture and galvanization for the cure of certain cases of myopia. There is one case, having considered one needle into the ophthalmic nerve, and another into the optic maxillary, he brought the needles into repeated contact with the two poles of a Voltaic pile. In a fortnight the patient had received considerable benefit from the pain. Other cases are also recorded in favour of this treatment.—See *Journal of the Royal Society of Medicine*, 1904, p. 126 of 1904.

[illegible]

by James Ware. Inquiry into the causes preventing success in the cultivation of the Chestnut, &c. by the same. Overlaid with Malabar cloth, 4th ed. A. J. Spon, Paris, 1844. This book has gone through many editions in Italy. The last, which is much improved, has been well translated by Mr. Briggs. W. H. p. in *Practical Observations on Surgery, and Med. Diet. and Inquiry*, vol. 5. Schewcher's *Wundärztliche Vorlesungen*, &c. p. 272. *Meister's Jahrbuch für die Naturgeschichte*, &c. p. 5. *View on the Diseases of the Eye*, by Wilson, New York, vol. 2, 1850. Some critical remarks on the posthumous work on the Diseases of the Eye of the late J. C. Sammler, by Dr. Arnold, *Mémoires de l'Académie de Médecine de Paris*, 1844. J. Stearns, *On the Structure, &c. of the different Species of Anomura*, Nov. 1821. 6. *Treatise on the Squamous of the Dura of the Eye*, by David Lewis, 1834. *On Sarcosis's Junctions on Dissection of the Eye*, the reproduction of which in a separate form, with references to the first works and authorities, would make up if the most useful books on the subject.

Many additional observations, connected with the subject of animals, will be found in the articles Cataract, Diplopia, Fungus Haemorrhoides, Graft Serum, Hematocopia, Hemidysia, Nyctipopia, Sign. Deform of, &c.

AMBE. *Artemia* *Artemia*, the projecting edge of a rock, an old charrminal machine for relieving dislocations of the shoulder, and so called because its extremity projects like the prominence of a rock. Its invention is ascribed to Hippocrates. The trace in the most ancient mechanical contrivance for the above purpose; but it is not at present employed. Indeed, it is scarcely to be met with in the richest cabinets of surgical apparatus. It is composed of a piece of wood, rising vertically from a pedestal. With the vertical piece is articulated, after the manner of a hinge, a horizontal piece, with a gutter formed in it, in which the located limb is laid and secured with straps. The patient places himself on one side of the machine. His arm is extended in the gutter and secured; the angle formed by the union of the ascending piece and by the horizontal branch is lodged in the strap, and then the horizontal branch is depressed. It is now extended to the side, while the vertical part makes constant extension, and an superior part tends to force the head of the humerus into the articular cavity. But there is nothing to fix the scapula, and the compression made by the superior portion of the vertical piece of the machine tends to force the head of the humerus into the glenoid cavity, before it is well disengaged by the extension. — See *Boyer on Dissections of the Bones*, vol. 2.

AMBLYOPIA. From *amblyo*, dull, and *opsis*, the eye. Hippocrates means by this word, in his Aph. 21, sect. 3, the darkness of sight to which his pupils are subject. Modern writers generally understand by *amblyopia* *myopia*, *asthenopia*, or the weakness of sight attended with certain stages and forms of *lilas obscura*.

ADDONIA MURINA, ADDONIA MURINATA. Sol
arrivato. The chief use is surgery, as in an internal
cervical application.—(See Loco ADDONIA. Murina
(see Aorta.)

Mr. Juchaczewski recommends the following application in such abscesses: 6. Abscessus maxillae Tj. Squatina terna marina Sp., Muench. Lichen sage are to be used with the remedy, and kept continuously applied to the part affected.

There can be little doubt of the utility of this being in describing the information left after variously assumptions; but while these claims are underpinned with such such, however, and unfortunately, existing formalizations and methods are to be preferred.

If earthen of ammonia be mixed with its weight of powdered zinc, and dissolved in six or eight parts of water, it produces a very good farric, which may be used as a substitute for zinc in cases of strangled hernia.

AMPUTATION. The operation of cutting off a head, or other part of the body, as the *Amput. per. &c.*

Birth an opportunity frequently becomes a responsibility rather than the privilege of mere birth. A thought well used, for the sake of taking the only relevant chance of saving the trunk itself. Indeed the suggestion of this doctrine, in cases of identification, where there is no chance of the paper becoming, may be said to be derived from nature itself, who, by a process to which I shall advert in speaking of justification, directs

the soul from the living pain; this separation is followed by amputation, and the patient recovers.

The necessity for amputation has always existed, and ever will continue, as long as the destructive effects of injuries and diseases of the limbs cannot be arrested in any other manner. An Greek surgeon, *Strabo*, who was more a poet than a physician, about forty years ago, when the operation was more frequently practised than at present, and this fact is to be ascribed less to the ravages of syphilis than to the imperfection of the medicine which used to be employed for the fatal local diseases. For these diseases of the limbs, and some other cases, at present treated with success, were always deemed incurable without amputation. *Boissier*, *Gottsch*, *Four*, and *Rigault* struggled against the frequent performance of amputations on the head of public, and their arguments were more of little value; when a path were at the same time traced which would conduct us to the method of curing the evil circumstances which form the necessity for the operation. When this condition is fulfilled, and more efficient modes of treatment are devised, as for instance with respect to the gun-shot wounds specified by *Rigault*, then the necessity for amputation in such cases would cease of itself.—*Neuman für die Abhängig gewisser Krankheiten*, p. 12, 8vo. Berlin, 1822.

As the author of another valuable modern work has said, it is an excellent observation, founded on the patient humanity, and justified by the soundest professional principles, that in next one limb is inflicting more miserable in the surgeon, than to have performed hazardous amputations, between successful; but it is a fearful, but not unkindly, question, fully as true, that it is much better for a man "to live with three limbs, than to die with four."—*Hutton on Military Surgery*, p. 251, ed. 2.

To this saying should be added the reflection, that some unfortunate beings, informed by a false belief, have been known to submit to the loss of all their legs and arms, and yet recover. In the *Journal des Invalides* at Paris, mutilated objects are to be seen, who had lost all their limbs and arms so that, unless assisted, they could not see, and it was necessary to feel and walk upon them like new-born infants.—*Mémoires Opus*, de *Chir.* p. 185, and *Gratich*, op. cit. p. 22.

The amputation of the large limbs was severely punished under many disadvantages. The best way of making the incisions was unknown; the ignorance of the skill surgeons about the right method of stopping hemorrhage was the cause of a large proportion of the patients who had courage to submit to the operation; the mode of holding the wound by the first assistant was not understood, as we daily experienced; and the instruments were so awkward and clumsy, as the drawings were evincing and disgusting.

Modern practitioners have judiciously displayed all the chief operations in surgery; an object which has been accomplished not rarely by setting anatomical science to the main guide of their proceedings, and, simply by devising more painless and less painful methods; not only by diminishing the number, and improving the construction, of instruments; but also, in a very essential degree, by abridging the use of a multitude of external applications, most of which were useless or harmful.

The Greek, Roman, and Arabian practitioners attempted limbs with feelings of alarm, and, in general, with the most barbarous results, while modern surgeons proceed to the operation with feelings of horror, well knowing that it mostly gives *misericordia*, hence, as *Gratich* justly remarks, nothing can be more evident, than that the patient's safety must depend very much upon the kind of practice.—(*See Neuman für die Abhängig gewisser Krankheiten*, p. 12.) By practice is here implied the mode in which the operation is performed, the way in which the wound is dressed, and the whole of the after treatment.

It is much improved as amputation has been, it cannot be denied, that it is an operation as once terrible to bear, dreadful to behold, and sometimes severe and fatal in the consequences which it itself produces, while the patient, if saved, is left for ever afterwards in a crippled, mutilated state. Hence it is the surgeon's duty never to have recourse to so serious a proceeding without a perfect and well-grounded conviction of its necessity. Amputation should be generally regarded as the last expedient to which a surgeon ought to re-

sort; an expedient justifiably, as a late writer says, only when the part is either already gangrenous, or the seat of so much injury or disease, that the attempt to preserve it any longer, would expose the patient's life to the greatest danger.—*Dict. des Sciences Méd.* t. 1, p. 672.

Although, says a distinguished modern surgeon, this amputation is a confession, that the case of some local diseases is not within the limits of our art, yet, on the other hand, it furnishes a proof, that surgery may be the means of saving life under circumstances which, without its assistance, would inevitably have a fatal termination. The physician is adapted to the moral treatment; the nurse is exerted for the prevention of complications.—*Gratich*, op. cit. p. 18.

Nothing can be more almost or more misapprehended, than the confusion sometimes passed upon amputation, because the body is mutilated by it. And, although, as a modern writer remarks, the operation proves the limitation of human knowledge and ability, it must be very unfair on this account to throw blame on surgery, or the practitioners who thus serve the patient's life. For, without dwelling upon the fact, that a humane surgeon would never amputate through a mere love of operating, and without regard to value, one may safely ask, are his diseases in their nature curable? Does not the surgeon even sell as an exorable without consideration? And are not cases, which were in the beginning curable, often first brought to the surgeon, when, from neglect, they have become totally incurable? Is it not his duty then to employ the only means left for saving the patient? And is not the preservation of a weak and feeble life a compensation for the sacrifice? Would it not be just as reasonable to blame an architect, when the irretrievable loss of labour, or a bomb destroys his building? Indeed, is it not rather a greater honour to surgery, that even when death has already taken possession as it were, of a part, and a threatening inevitable destruction to the whole, it means to yet preserve not only of saving the patient's life, but of bringing him into a state in which he may recover his former good health?—*Erwinckmann, Entzündung und Hämorrhagien über die Amputation*, p. 11, 8vo. Berlin, 1818.

Though amputation is in every respect much better than in former times, and its right performance is by no means difficult, I would not wish to be thought to say, that it is always, or even usually done according to art, besides long opportunities of observation have convinced me of the contrary; and the remedy of the knife being not so fully handled in the part of surgery, may generally be ascribed to confusion, stupidity, laziness, or, what is as bad, a want of ordinary despatch. There are several egregious faults in the method of amputating, which even every hospital surgeon in this metropolis are guilty of; but these we shall find, when we discuss them, are for the most part easily avoidable, without any particular share of skill being required. A greater difficulty is to ascertain with precision, the cases which demand the operation, those in which it may be dispensed with, and the exact periods at which it should be performed. These are considerations requiring profound attention, and the highest talents. The most expert operator as Mr. O'Halloran observes, may not always be the best surgeon. To do justice to the work and operation, we must, in many cases, rather avoid this perfect surgical operations; and with respect to amputation, it we consider the many cases in which it has been unnecessarily undertaken, or done at unreasonable periods, it may be supposed, that this operation, upon the whole, may have done more mischief than good. At all events, it is not enough for a surgeon to know how to operate; he must also know when to do so.—*See O'Halloran on Gangrene and Suppuration*, p. 100.

For such reasons I shall first take a view of the circumstances, under which the best surgeons deem amputation necessary; though it may be proper to observe, that in each of the articles relative to the particular diseases and injuries which ever call for the operation, additional information will be offered.

I. Compound Fractures.

In a compound fracture the necessity for amputation is not altogether pronounced to the advantage of the accident, but still frequently depends at first upon other circumstances. For example, if the ball, and

on board of a crowded ship, it is not constantly in the surgeon's power to pay such attention to the cases demand, nor to provide for the patient the proper degree of rest and good accommodation. In the field, there is often a necessity for transporting the wounded from one place to another. Under these circumstances it is proper to have immediate recourse to amputation, in numerous cases of bad compound fractures, where of which, perhaps, might not otherwise cleaved the system, when the patient is so situated, so it is capable of feeling all the advantages of the best and most scientific treatment in a well-ventilated quiet house of hospital, furnished with every desirable convenience. At the same time daily experience proves, that there are many other cases, in which it would be improper to have recourse to the knife, even under the most unfavorable circumstances of the above description. So, when a compound fracture occurs, in which the soft parts have not been considerably injured; in which the bones have been broken in such a direction that they can be easily set and kept in their proper position, or in which there is only one bone broken, amputation would be unnecessary and cruel. But when the soft parts have been more extensively hurt, and the bones have been so badly broken, that perfect quietude and cleanliness cannot be required to afford any chance of recovery, it is a good general rule to amputate whenever these advantages cannot be obtained.

The bad air in crowded hospitals and large cities, a circumstance so detrimental to wounds in general, is another consideration which may seriously lessen the chance of curing a badly broken limb, and should be considered in weighing the reasons for and against amputation.

On this part of the subject, I feel the sentiments of Grant interesting. Besides an abstract, says he, there is a relative necessity for amputation: it is the most successful, and provides altogether the most satisfactory external circumstances, though, alas! in many cases hardly ascertainable, when life is to be preserved. In war, every loudly uttered phraseology of what has been stated. The number of the wounded to amputate; the number of surgeons for the day too limited. The surgeons must travel as at a distance. In these emergencies, though the military surgeon may, from nature and practice, be able to suggest the quickest method of obtaining what is wanted, know how to avail himself of every advantage, which circumstances present, and estimate tolerable substitutes for such things as are deficient, yet this will not always do. Were we, says Grant, here to complain of the government not providing due assistance for the defenders of our native soil, to assure the necessaries would only appear ridiculous. Yet they who manage the medical affairs of the Prussian army may not immediately have it in their power to avoid the inconvenience. The general cannot decide the number and service of the wounds which may happen, so as to enable the medical department to take with them exactly the apparatus required, without endangering the army with a subsistence of useless articles. The enemy, perhaps, captures the medical stores, or the rapid movements of particular corps cut them off from the principal depots. Details must often be sent at remote points. The hospitals may be several miles in the rear of the line; and, for want of means, the transport of the imperfectly-dressed wounded may continue night and day. Hardly are the sufferers brought into the nearest hospital, in the most painful state from pain, anxiety, and cold, when an order is given to break up, and they must be conveyed still further towards their grave; and a thousand other circumstances, as Grant observes, which deprive the wounded of the requisite attention and essential number of surgeons, together with the most necessary stores, make it desirable to stipulate every wound as much as possible; when, indeed, is the only reason of stipulating this, perhaps, that, while we are endeavoring to save one man's limb, we let another die.

Who doubt, says Grant, that a soldier with a gunshot wound, complained with a shocked state of the wound, may sometimes be saved, without loss of his limb, by employing all the means which the resources of surgery offer? But these very resources are often wanting in a campaign; and the business of dressing the patient would occupy the surgeon several hours daily, during which his useful assistance could not be extended to other sufferers. Notwithstanding this

most care, the removal of patients from one place to another frequently renders their wounds extremely dangerous, or fatal; and we now lose many a man, who, had he undergone amputation, would have been able to bear the journey.—See *Northern Star* for the following interesting observations, p. 15, 16.

From what I have seen of the ill effects of moving patients with bad compound fractures of the lower extremities, produced by gunshot violence, I am convinced that, as a general rule, it is better to perform amputation; but if that be not done, and an attempt is to be made to save the member, it will be more fortunate, when the army is retreating, and the enemy are not savages, to move such wounded behind, than subject them to all the trials and trials of hastily and roughly transporting them in such a condition. It gives the party sent forward to find the preceding regiment, commanded by Dr. Hensley, whose knowledge and experience in military surgery enable all his opinions to be given with the greatest confidence; in noting what ought to be done with the wounded, when the army is compelled to retreat, he says, "It is that increases the duty of a certain proportion of the hospital staff to devote themselves to their wounded, and become prisoners in war along with them, and in that, so as to ensure success in the art, experience, while it is painful to me, to believe that I have never witnessed, nor heard of, inquiry, all act of unnecessary severity practiced rather by the French or British armies on these wounded prisoners."

Compound fractures of the thigh, produced by gunshot violence, too often have an unfavorable termination, especially when the wound has been caused by gunshot or even a stoneball, fired from a moderate distance, and the patient is moved from one place to another after the receipt of the injury. In the military hospital at Glendaloch, in the spring of 1818, I had charge of about eight bad compound fractures of the thigh, of which cases only one enjoyed a final termination. This was an instance in which the wound was situated a little way above the knee. Another patient was relieved by amputation; the perils immediately arising from the effects of displaced state of the bone, the excessive injury of the tissues, and current abscesses, but was unfortunately lost by secondary hemorrhage. All these patients had not merely been struck by gunshot, or else by balls fired from a short distance, but they had been moved from Bergen-op-Zoon into my hospital five or six days after the receipt of the injury, the very worst period possible in a wound of the inflammation being then most violent. From the ill success of these cases, many a surgeon, who saw them, might be inclined to think that immediate amputation, ought generally to be performed for all compound fractures of the thigh so soon after the receipt of the injury as possible. And such is my own sentiment, whenever the accident has been caused in the system I have above specified, or whenever the patient must be moved any distance in a wagon after the occurrence of the injury. It may be right to state, however, that I have known more than one compound fracture of the thigh cured, when the accident had not been occasioned by gunshot violence, and I have been informed of one or two successful cases where the bone was broken by a pistolball. In St. Bartholomew's hospital, two compound fractures of the thigh were pointed out to me some time ago, as cases likely to end favorably. However, these may only have been lucky escapes, deviations from what is common, and not entitled to any stress, with the view of affecting the general excellent rule of amputating where the thigh-bone is broken by gunshot violence.

As Mr. Galt has accurately observed, one circumstance which increases the danger of fractures of the thigh from gunshot violence is, that the bone is very often broken obliquely, the fracture extending far above and below the point immediately struck by the ball.—*On Gunshot Wounds*, p. 191, 192. This disposition of the thigh-bone to be fractured by several inches when hit by a ball, and the violent danger arising from the occurrence, are also very particularly commented upon by the experienced observation, who has been surgeon-general to the Prussian armies in the campaigns of Frederick the Great.—See the *Vermischte Chirurgische Schriften*, t. 1, p. 39, 40, Berlin, 1763. In several of the cases under the care of Dr. Cole and myself in Holland, the bone was split lengthwise to the extent of seven or eight inches.

According to Schramm, all fractures of the middle or upper part of the tibia are attended with great danger. "But says he, if the fragment be situated at the lower part of the bone, the risk is considerably less, the fragment almost being as powerful, in such a case, therefore, amputation would not be performed before every other means are lost; being tried, and very frequently I have treated fractures of this kind with success, though the risk sometimes occurred still. But says Schramm, if the bone is completely fractured or splintered by a ball at its middle, or above that point, I never was for the bad operation to commence, but amputate ere they gangrene, and when the operation has been done early, even if, most of my patients have been cured. However, when some days had transpired, and inflammation, swelling, and fever had come on, I would usually caution them the issue was not always fortunate. Yet the operation should not on this account be diagnosed with; for if only a few days this is waited out of easily, some benefit is obtained, as, without this step, such few would also perish."—*Vermischte Chir. Section 2. l. p. 12.* When I have of compound fractures of the thigh, after the accident on Bergen-*op-Zoom*, we may remark, sometimes with the assistance of Schramm's single experience; on the only two patients who survived the bad symptoms proceeding directly from the fracture were, one whose femur was broken near the knee, and another whose limb I took off as an account of a fracture of the middle of the bone, accompanied with abscesses of surprising extent. The latter was a man, twenty, in which the limb ought to have been repaired earlier. The following remarks, by Mr. Galtier, I consider judicious and correct.

"The danger and difficulty of cure attendant on fractures of the femur from gun-shot wounds, depend much on the part of the bone injured; and in the consideration of these circumstances it will be useful to divide it into five parts. Of these, the first and neck included in the capsular ligament, may be considered the first; the body of the bone, which may be divided into three parts, and the apical portion of the lower end of the bone exterior to the capsular ligament, forming the fifth part. Of these, the fractures of the first kind are, I believe, always ultimately fatal, although life may be prolonged for some time. The upper third of the body of the bone, if badly fractured, generally causes death at the end of six or eight weeks of acute suffering. I have seen few cases, and then not with a useful limb that had been badly fractured in the middle part. Fractures of the lower or fifth division are in the next degree dangerous, as they generally affect the joint; and the lower diagnosis are fractures of the lower third of the body of the bone. Of these even I do not mean to conceal, that when there is even slight tenderness the danger is great, so that a fractured thigh by gun-shot, even without particular injury of the soft parts, is one of the most dangerous kinds of wounds that can occur."—*See Galtier on Gun-shot Wounds, p. 120.*

In compound fractures, as Mr. Pott has correctly pointed out, there are three points of time when amputation may be proper. The first of these is immediately or as soon as possible after the receipt of the injury. The second is, when the bones contain the great length of time without any disposition to unite, and the discharge from the wound has been so long and so large that the patient's strength fails, and general symptoms denoting disorganization come on. The third is, when a suppuration has taken such complete possession of the soft parts of the inferior portion of the limb quite down to the knee, that upon the separation of each part the bone or bones shall be left bare in the extremity.

The first and second of these are matters of very serious consideration. The third hardly requires any.

When a compound fracture is caused by the passage of a very heavy body over a limb, such, for instance, as the broad wheel of a wagon or loaded cart, or by the fall of a very ponderous body on it, or by a cannon-shot, or by any other means so violent as to break the bones into many fragments, and so to tear, bruise, and wound the soft parts, that there shall be good reason to fear that there will not be power sufficient to carry on the organization with the parts below the fracture, it becomes, as Mr. Pott observes, a matter of the most serious consideration, whether in attempt to save

such a limb will not involve loss of life. This consideration must be before any degree of inflammation has spread the joint, and that the best is to immediately after the knowledge. When inflammation, tumour, and disposition to gangrene in the limb have arisen, the patient is highly disagreeable for operating, and the patient's situation at being seized by gangrene under these circumstances are much smaller than before the discharge has brought bad takes place. At the same time, there are certain examples of institution from external causes, when, as far as the can judge from the results of later experience, as that of Mr. Pott, the surgeon should not defer amputation, even though the disorder be put in a gangrenous state attended with considerable swelling and serious tendency for up the limb. This is a slight, however, which will require more explanation hereafter.—But what is presently sought is Mortification; nor are the cases to which reference is made meant to affect the general tenor of the observation delivered by the most experienced surgeons of every age, that when a limb is almost very wasted and stiffened, with a part of it either in a state of spreading mortification, or ready to become gangrenous, the period is so unfavorable for amputation, that very few patients so circumstanced ever recover after the operation. Nor is it meant to be insinuated, that in the very cases which form exceptions to the general rule of not amputating before the tendency to gangrene has ceased, the patient might not have had an entirely better chance of his life, had the operation been done immediately after the first receipt of the injury, before any disposition to gangrene had had time to be produced.

The necessity of amputation or very early dissection, in these cases makes it a very delicate part of practice; for however pressing the case may seem to the surgeon, it will not, in general, appear in the same light to the patient, to the relations, or to himself. They will be inclined to regard the proposition as arising from ignorance, or an inclination to save trouble, or a desire to operate; and it will often require more firmness on the part of the practitioner, and more resignation and confidence on the part of the patient, than is generally met with, to submit to such a severe operation in such a serious injury, and upon so little apparent deliberation; and yet it often happens, that the suffering and point of time to pass decides the patient's fate.

The necessity of many dissections arises from the quick tendency to mortification which exists in the injured limb, and too often ends in the patient's death. That this is no exaggeration, says Pott, immediately and frequent experience evinces, even in those whose conditions previous to the accident were in good order; but such state in these who have been treated by violent exercise, or labour, or fatigue, or who have led very debauched and unregular lives, or who have habits usually intemperate and irritable. This is often the case when the fracture happens in the middle part of the bone, but is much more likely to happen when any of the large joints are concerned. In many of these cases a determination for or against amputation is really a determination for or against the patient's existence.

That it would have been impossible to have saved some limbs which have been cut off as soon as they presented to any; but this does not render the practice imprudent. Do not the majority of those who get into the above fatal condition, and whose dissections are not performed, perish in consequence of their wounds? Have not many even been preserved by amputation which, from the same circumstances, would otherwise most probably have been lost?

Pressing and urgent as the state of a compound fracture may be at this first point of time, and it will be a matter of choice whether the limb shall be removed or not; but at the second period the operation must be submitted to, or the patient must die.

The most disagreeable appearances at first do not necessarily or constantly end unfavorably. Sometimes, after the most threatening first symptoms, after considerable length of time, great discharges of water and large exfoliations of bone, various shall ultimately be removed, and the patient shall recover the limb and the use of his limb.

But sometimes after the most judicious treatment through every stage of the disease; after the united efforts of physic and surgery; the case, instead of gratifying kindly, and continuing daily to be smaller

the shall remain as large as at first, with a raw, spongy surface, discharging a large quantity of thin mucus, instead of a small one of good matter; the fractured ends of the bone, instead of uniting to exclude pyætic matter, will instead so perfectly loose and detached as at first, while the patient shall lose his sleep, his appetite, and his strength; a hectic fever, with a quick, weak, hard pulse, profuse sweats, and delirious purging, continuing at the same time to bring him to the brink of the grave, notwithstanding every kind of abstraction: in these circumstances, if amputation be not performed, Mr. Pott asks, what else can preserve the patient from destruction?

The third and last period is a matter which does not require much consideration. Too often the inflammation consequent upon the injury, instead of producing abscess and suppuration, tends to gangrene and mortification, the progress of which is often so rapid, as to destroy the patient in a very short space of time, notwithstanding that very act of cure in which amputation should have been immediately performed. But sometimes even this dreadful malady is, by the help of art, put a stop to, but we trust it has totally destroyed all the surrounding vessels, tendons, and sometimes quite down to the bone, which, upon the supposition of the united parts, is left quite loose, and all circulation between the parts above and those below is by this totally cut off. Is this sufficient whether the stump may through the bare bone or bone the membrane to be affected by matter, the patient must lose his limb.—See Pott's Remarks on the Necessity, &c. of Amputation in certain Cases, &c. Chir. Works, vol. 2.

For the consideration of a variety of complicated cases which affect the question of amputation in compound fractures, I must refer to the article Gunshot Wounds.

2. Extremities perforated and lacerated wounds.

These form the second class of general cases requiring amputation. Wounds without fracture are not often so bad as to require this operation. When a limb, however, is extensively comminuted and lacerated, and the principal bloodvessels are injured, so that there is no hope of a continuance of the circulation, the immediate removal of the member should be recommended, whether the bones be injured or not. Also, since no effort on the part of the surgeon can prevent a limb so injured, and such wounds are more likely to mortify than any others, the sooner the operation is undertaken the better.

In these cases, as in those of compound fractures, though amputation may not always be necessary at first, it may become so afterwards. The foregoing observations, relative to the second period of compound fractures, are equally applicable to badly lacerated wounds, attended with injury of the bones. Sometimes a rapid mortification comes on; or a putrid suppuration, which the system can no longer sustain.—(Cyclopædic Methodique; *parle Chir.* t. 1, p. 86.)

2. Cases in which part of a limb has been carried away by a cannon ball.

When part of a limb has been torn off by a cannon-ball, or any other cause capable of producing a similar effect, the formation of a good and serviceable stump, the greater facility of healing the clean, regular wound of amputation, and the benefit of a far more expeditious, as well as of a surer cure, are the principal reasons which here make the operation advisable.

This was an instance, in which some former surgeons disputed the necessity of amputation. They, urged as a reason for their opinion, that the limb being already severed, it is better to endeavor to save the wound as speedily as possible, than increase the patient's sufferings and danger, by making him submit to amputation. It must be remembered, however, that the bones are generally shattered, and reduced into numerous fragments, the tendons and vessels are completely divided, and their ends torn and confused. Now, none of the old surgeons questioned the absolute necessity of extracting the splinters of bone, and cutting away the irregular extremities of the tendons and vessels, which operations would require a longer time than amputation itself. Besides, we should recollect that, by making the incision above the injured part, so as to be enabled to cover the bone with flesh and membranes perfectly free from injury, the extent of the

wound is at diminished, that the healing can be accomplished in one-third of the time which would otherwise be requisite, and in which former cases is also obtained. Such operations must therefore be, that amputation here holds forth very great advantages. It cannot increase the patient's danger, and as for the necessary sufferings of pain which he suffers, he is amply compensated by all the benefits resulting from the operation.—(See Gunshot Wounds.)

4. Mortification.

Mortification is another cause, which, when introduced in a certain degree, renders amputation indispensably proper. When introduced, too, and progressed fractures and wounds often terminate in the death of the individual. Such surgeons as have been distinguished, at all events, to oppose the performance of amputations, have maintained, that the operation is here totally useless. They assert, that when the mortification is only in a slight degree, it may be cured, and that when it has spread to a considerable extent, the patient will perish, whether amputation be performed or not. But this way of viewing things is so contrary to facts, and the experience of every rational practitioner, that I shall make no attempt to refute the assertion. While it is allowed that it would be very bad practice, to postpone an every slight appearance of gangrene, it is equally a fact, that when the disorder affects the substance of a member, the operation is generally the safer and most advantageous measure. Nay, there are, as we shall presently see, certain forms of mortification, in which the early performance of amputation is the only chance of saving the patient.

Practitioners have entertained very opposite opinions, concerning the period when one should operate in cases of mortification. Some contend that whenever the disorder presents itself, and especially when it is the effect of external violence, we should amputate immediately; the mortification has decidedly begun to form, and while this mischief is in a spreading state. Others believe, that the operation should never be undertaken before the progress of the disorder has stopped, even not till the dead part has begun to separate from the living one.

The advocates for the speedy performance of amputations declare, that the farther progress of the mortification may be stopped, and the life of the patient preserved, by cutting above the part affected. However, according to the reports of the greater number of experienced surgical writers, this practice is highly dangerous, and unbecoming of conviction. Whenever pain may be taken, in the operation, only to divide sound parts, there is no certainty of succeeding in this object, and the most skilful practitioner may be deceived. The skin may appear to be perfectly sound and free from inflammation, while the tissues which it covers, and the parts immediately surrounding the bone, may already be in a gangrenous state. Between when the soft parts are found free from apparent disorder, and making the incision, still, if the operation should not have waited till the mortification has ceased to spread, the stump will almost always be attacked by gangrene. Surgeons who have had opportunities of frequently seeing wounds which have a tendency to mortify, entertain the latter opinion. Such was the sentiment of Pott, who says that he has often seen the experienced mode of amputating a limb in which gangrene had begun to show itself, but never saw it succeed, and it invariably hastened the patient's death.

The operation may be postponed, however, too long. Mr. R. Sharp, in particular, recommended the much delay, advising the operation never to be done, till the natural separation of the mortified parts had considerably advanced. Mr. Sharp was a witness of numerous operations, and his authority carries with it the greatest weight. But, perhaps, he was too weak in his opposition to a practice, the peril of which he had so often beheld. When the mortification has ceased to spread, there is no occasion for further delay. We have stated, just as certainly, all the benefits of the operation, and got rid of a mass of pathology, the calculations from which justify the amputation which the patient breathes, and are highly detrimental to his health. Nay, according to the reports of writers, patients in these circumstances may actually fall victims to the absorption of the putrid matter which is suffered to remain too long. However, this danger would not be

[illegible]

*The University and other institutions of America, and its
future development.*

Cancerous metastases, however, and malignant intracranial tumors in the brain, sometimes cause an irritation or a state of anxiety, or a feeling of constant, or slight, constant pain, but in no instance can be proved either to be internal or any kind of organic condition, and there is nothing, except the total separation of the part affected, cases where any rational hopes of cure can be held. Cancer is not frequently seen on the extremities. Every case of cancerous tumours, however, sometimes have seen in the situation, if not actually cancerous disease, pain or irritation, and which cannot be cured except by removing the affected part. This may often be accomplished without cutting off the whole limb. But when the disease has spread beyond certain bounds, amputation above the part affected is the only thing in which recovery can be had with any hope of success. Sometimes, when the operation has been delayed too long, even amputation itself will not effect a cure. In a few cases of finger amputation, the operation has succeeded, however, after the disease had disappeared, and a cure had been seemingly achieved by the removal of the diseased part. Yet, from what I have seen of finger amputations, I should much rather believe the best is achieved by amputation would be sooner, as when this disease shows itself only externally, internal organs are rarely or the more true statement affected.—*Rev. Francis H. Stoddard.*

Because computers, there is a great need, which may be considered a political problem. Thus, when an extensive study of any sort whatsoever, is actually completed, the health benefits instead of pointing to new ideas, it becomes larger and more (infinite) extent, in short, it puts life in a new danger; argumentation should be a friend.

6. *Gamma* *Gamma*.

That there are numerous seedlings, which destroy the foliage of the tree by sucking their juices, says a very doubtful statement, and bringing the patients into the most deluded state, by that of superstition sustained by them. When such persons get neither the depressed one, nor get with safety, respiration of the lungs is not very common.

Mr. Pitt has particularly described a flower affording the key to which the operation is sometimes successful. It was so near to the middle of the leg as rather more towards its apex, just under the gastrocnemius and tibiae crurales. It begins by a small, hard, deep-seated swelling, sometimes very painful, sometimes less affixed, and may increase very

patient's recovery. It does not alter the natural color of the skin, at least until it has attained a considerable size. It enlarges gradually, does not soften as it enlarges, but contracts through the greater part of it is inconspicuously hard, and when it is put to a large size it seems to contract a fluid, which may be felt towards the bottom, as pulsing, as it were, on the back part of the tumor. It is an opening to enable for the discharge of the fluid; it must be made very deep, and through a strictly disorganized mass. This fluid is generally coral in quality, and consists of a serum mixed with gelatinous fluid; the discharge of it produces very little alteration of the tumor, and very high symptoms of suppuration and inflammation come on, and, advancing with great rapidity, and most exquisite pain, very soon destroy the patient, either by the fever, which is high and unrelenting, or by a mortification of the whole leg. If suppuration has not been procured, and the patient dies after the tumor has been freely opened, the inverted and partial state of the parts presents all the symptoms of suppuration; but if the fluid was removed, without any previous section, and which Mr. Parr, in his experiments, found to be the only way of procuring the patient's life, a suppurated fluid artery will be found to be enlarged, disorganized, and hard; the remainder of the vessel to have been converted into a stringy fibrous mass; and the posterior part of both the iliac and ilio-lumbar to be contracted.—PARR ON ANEURISM.

It seems only necessary to add, another species of tumour to illustrate the form of angiosarcoma. The following case is related by Mr. Abernethy. A patient was admitted into St. Bartholomew's Hospital with a hard tumour in the arm. It was about five inches in length, and three in breadth. One had also a tumour in front of the thigh, a little above the patella, of four or five in diameter. The tumours in the arm, by its pressure on the superficial vessels, had greatly lessened the sensibility, and obstructed the circulation of the leg, so that the limb was very edematous. As it appeared dangerous to preserve the patient, and his age and constitution were advanced, amputation was performed. On examining the amputated limb, the tumour in the arm could only be divided with a saw. Several slices were taken out of it by this means, and appeared to consist of a conglomerate and vascular substance, in the intervals of which a great deal of honey matter was deposited. The remainder of the tumour was incised and dried, and is appeared to be formed of an irregular and compact deposition of the walls of blood vessels. The tumour on the front of the thigh was of the same nature as that of the arm, but contained no little fluid, so that it could be put with a knife. The thigh bone was not at all diseased, which is mentioned, because, when honey matter is deposited in a limb, it is generally arising from the disease of a bone.—*Surgical Observations*, 1804.

Before the late thirties and improvements relative to the treatment of aneurysms, these cases, on the extremities, were generally set down as requiring amputation. Even Mr. Pott, and J. L. Petit, wrote in recommendations of such practice, and their observations on this subject are among the few parts of their writings which the enlargement of surgical knowledge, since those times, has rendered dispensable. The surgeon is seldom the knower of first principles, this erroneous doctrine belongs to A. N. Goussard, who opposed the advice dictated on this subject by Petit.—*Häufig Recid. Chir.* vol. 3, p. 103.

A third example of these remarks on the cases regarding inspiration, with advancing purposes, serves to illustrate this serious situation, without considering the opinions of other environmentalists, who are not of the view as he demands. The best operators are those of course in that involving the kind of judgment by which the more absolutely demanding inspiration has been considered from others, in which the question may be merely postponed, and a chance of pursuing the right.

The kind of animals were not native to the region, and even a casual naturalist might have noticed the foreign-looking animals. The Aztecs had, for example, a variety of birds, including the turkey, which was a common food source. The Aztecs also had a variety of animals, including the dog, which was a common pet and a source of food. The Aztecs also had a variety of plants, including the corn, which was a staple food. The Aztecs also had a variety of tools, including the stone axe, which was a common tool for cutting and chopping. The Aztecs also had a variety of weapons, including the spear and the bow, which were used for hunting and warfare. The Aztecs also had a variety of clothing, including the tunic and the skirt, which were made of cotton and wool. The Aztecs also had a variety of jewelry, including the necklace and the bracelet, which were made of gold and silver. The Aztecs also had a variety of art, including the pottery and the sculpture, which were made of clay and stone. The Aztecs also had a variety of music, including the song and the dance, which were performed at festivals and ceremonies. The Aztecs also had a variety of games, including the ball game and the board game, which were played for entertainment and competition. The Aztecs also had a variety of religious practices, including the sacrifice and the prayer, which were performed to the gods. The Aztecs also had a variety of social structures, including the family and the community, which were based on kinship and shared resources. The Aztecs also had a variety of economic activities, including the agriculture and the trade, which were essential for their survival and growth. The Aztecs also had a variety of cultural achievements, including the calendar and the writing system, which were developed by their scholars and priests. The Aztecs also had a variety of historical events, including the conquest and the fall of their empire, which were recorded by their chroniclers and historians. The Aztecs also had a variety of legends and myths, which were passed down from generation to generation. The Aztecs also had a variety of customs and traditions, which were unique to their culture and identity. The Aztecs also had a variety of values and beliefs, which shaped their worldview and behavior. The Aztecs also had a variety of challenges and struggles, which they overcame through their resilience and determination. The Aztecs also had a variety of successes and achievements, which they celebrated with pride and joy. The Aztecs also had a variety of relationships and connections, which they maintained with their neighbors and allies. The Aztecs also had a variety of roles and responsibilities, which they fulfilled with dedication and skill. The Aztecs also had a variety of dreams and aspirations, which they pursued with passion and courage. The Aztecs also had a variety of fears and anxieties, which they confronted with bravery and faith. The Aztecs also had a variety of joys and pleasures, which they enjoyed with gratitude and appreciation. The Aztecs also had a variety of sorrows and hardships, which they endured with patience and strength. The Aztecs also had a variety of hopes and expectations, which they held with optimism and faith. The Aztecs also had a variety of regrets and mistakes, which they learned from and grew from. The Aztecs also had a variety of loves and passions, which they cherished and protected. The Aztecs also had a variety of hates and dislikes, which they expressed and managed. The Aztecs also had a variety of friends and enemies, which they dealt with wisely and justly. The Aztecs also had a variety of secrets and mysteries, which they guarded and shared. The Aztecs also had a variety of wonders and marvels, which they explored and admired. The Aztecs also had a variety of adventures and discoveries, which they embarked on with curiosity and excitement. The Aztecs also had a variety of triumphs and victories, which they celebrated with honor and glory. The Aztecs also had a variety of defeats and losses, which they accepted with grace and humility. The Aztecs also had a variety of beginnings and endings, which they marked with ceremony and reflection. The Aztecs also had a variety of cycles and rhythms, which they followed and harmonized. The Aztecs also had a variety of patterns and designs, which they created and appreciated. The Aztecs also had a variety of colors and textures, which they used and enjoyed. The Aztecs also had a variety of sounds and smells, which they heard and smelled. The Aztecs also had a variety of tastes and smells, which they tasted and smelled. The Aztecs also had a variety of feelings and emotions, which they experienced and expressed. The Aztecs also had a variety of thoughts and ideas, which they thought and shared. The Aztecs also had a variety of actions and behaviors, which they performed and observed. The Aztecs also had a variety of interactions and relationships, which they engaged in and maintained. The Aztecs also had a variety of experiences and memories, which they lived and remembered. The Aztecs also had a variety of dreams and visions, which they dreamed and saw. The Aztecs also had a variety of hopes and dreams, which they held and pursued. The Aztecs also had a variety of fears and anxieties, which they felt and managed. The Aztecs also had a variety of joys and pleasures, which they found and enjoyed. The Aztecs also had a variety of sorrows and hardships, which they faced and overcame. The Aztecs also had a variety of loves and passions, which they had and cherished. The Aztecs also had a variety of hates and dislikes, which they had and expressed. The Aztecs also had a variety of friends and enemies, which they had and dealt with. The Aztecs also had a variety of secrets and mysteries, which they had and guarded. ing that remainder with a red-hot knife.—(Citation 10, p. 27, p. 48.) In the middle ages, little time was given to the preparation of dissections. In the 14th century some more systematic and more applied method supplanted a mere, so that an attention to cases related here presented themselves in which the principal means of not differing superficial rural examinations had come out, but in overlooking the matter by the operation, out it to have struck an intelligent surgeon. This might also expect that practitioners would now have been led to make the light and the sound dark. What formerly the attention of physicians and its immediate consequences in surgery, happened at a period when patients were all qualified to practise the art of medicine of experience and better than. The treatment of these practitioners furnished them with the first lesson how they ought to act, and these were themselves too easily convinced at the sight of the diseases of which they were reminded, so as to be able to form any correct opinion about causes and effects. Their first idea was, that the terrible symptoms proceeded from the parts being actually burned, and they afterward inclined to the belief that gas was towards were produced from the red charred matter of the burnt tissue collected, and, as this is a common experience, however, these names passed under a new veil, for which there were some cases as the place of origin.—(Schäfer, *deutsche der Antiquar.* 18.) This desperate state was the natural result of the depravity of science in general, and of the leading art in particular, at the epoch to which I now refer. In the middle ages, as they are called, the preparation of all Europe was plunged in the deepest ignorance, and wherever there was knowledge, whether of the arts or languages, was monopolized by the priesthood, the professors of those times, who, instead of studying the nature of nature, wasted most of their time in discussing the doctrines of fathers. Surgery itself sank to the lowest state, as may be well conceived from the curious account of Rhazes by Pope Innocent the Eighth, forbidding any of the clergy to do anything themselves which drew blood; and of course all the operative part of surgery, that which required the hand skill and science, was intrusted to a set of illiterate, low-down rascals, far inferior to the same country doctors of modern times. Yet the clergy, who were then universally devoted to making their own bodies well blood, or having their own bodies healed by viewing the signs of their own diseases submitted to surgeons, had no hesitation in seeing the physicians and doctors of the profession or in having over these poor sufferers to men more qualified to soothe and murder than to give relief; and, what nearly stamps all forcibly, the same professors of Christianity who continued to give a class of blood themselves on a proper occasion, as Haller observes, eagerly took a hand, and acted an important part, as they were naturally men, when it was possible for them to interfere. In these dark ages of surgery, the science delivered by Galien was removed by Theodorus, who used to practise upon men and brutes, previously to the operation, the purpose of rendering the patient less sensible to pain, and afterward vinegar had found a more agreeable way with the view of lessening the debilitating effects of the primary medicine.—(Citation 10, p. 12.)

[illegible]

At the end of the 19th century, the revival of learning occurred first in Italy. Now many began to study for themselves again, and physicians turned from conventional and scholastic medicine to the consideration of nature. Anatomy was calibrated with great ardour, and made brilliant progress under the strenuous character of the time: Be la Torre, Bolognini, Cenci, Vesalini, Fallopius, Rivisaviera, and others, who were able to do the most part very distinguished surgeons.

[illegible]

superior. To teach the method of applying medicine in cases of wounded soldiers and sailors was understood, yet from some uncontrollable causes the practice was never brought to its antiquations. Even Europeans knew of no other means for stopping the bleeding but cauterizing... De Tost, *op. cit.*, p. 612. On the whole, the stopping of bleeding was not intended with a degree of cautious proportion to the advances of the healing art in general. Straps, bands, and compresses

were indeed to seed the hatchery, but as the circulation of the blood was not yet correctly known, they were not applied in the proper places, being arranged either close to the wound, or several of them put at random round the fish. The effect of such ignominiously light, long-continued cauterisation could be nothing less than paralytic, and hence the actual cautery was still slowly employed. The safer means for suppressing hemorrhage would not yet have been known.

perished in the university and 21 emigrants of such importance, 2, in Vigo (Francisco in Chilivaca, Correas, 181, Barrio, 134), and Fabrice in Montevideo (19, 134). Verbe 1623, disapproved of suspending in the saint fish, and returned to the principle mentioned by the academy, of making the incision in the mortified parts. Others endeavored to lessen the pain of the incision by the application with which the fish was removed, and the instantaneous application of the same

ly. The tharsopore L. Donat invented a sort of pellicule, by means of which a tentacle was covered from the body as an insect (the *Cremaster subserpens* Linnaeus, Läng. 1759), whose whole last a stump was from the back, and effected the dismemberment by the force of a wooden mallet. An example of this tortuous process is revealed by *Polidura blanda*, called by its name again the pithy and movement of the German language. In consequence of the loss of blood-

before he knew of the cost of the ligature, he was fully acquainted with exposure with a red-hot knife, an representation of which is given in his work. — (The program of Syllabus, Op.) Hitherto became a further article, however, as he grew older, and as the end only contributed to the firmness of the operation, through as he made the business complete in the mind, and adopted the method of tying the arms, as they usually appeared in the case of the victims.

Andreasen, Mary, a Finnish immigrant, who flourished in the 19th century. (*Opera, Pianos, 162*), and is referred to in the *Historia*.—Op. p. 817. One of his friends was a friend that he met for the first time, and a letter mentioning his father, back the morning. *Amusing Speeches, Goodrich, Am. Char. p. 4, p. 467*, his observations on the past, presenting the opinions on the same.—Op. p. 807, 824.

the sloughs were as long as being thrown off. He applied a ligature round the limb, two inches above the point of the amputation, and, drawing up the muscles, made the incision with a large curved knife, with the back of which he scraped off the psoas muscle. The leg, as well as reflexor, employed by Falgout-Hill, was, without doubt, unnecessary, as the muscles spontaneously drew themselves up as soon as divided. He tied the blood-vessels after separation of the part, and discovered all kinds of the same. After the operation, he drew the flap over the bone, and after having done this in this position with stitches or a tight bandage, though he generally preferred the former, as the utmost means of keeping the end of the bone from protruding. Across the stump he laid a pledge of dress-wool, and over this a thick layer of Armenian balm and other styptics, and the whole was covered with a India's bladder and a roller, applied spirally from the upper part of the remaining portion of the limb down to the extremity of the stump. On the third day, the dressings were taken off, and a digestive dressing applied. — *Chirurg. Transact.* vol. 5, p. 299, 300, Lond. 1803.

From this time, expectation may be considered as being an infinitely safer proceeding than what it used to be. For, as we have explained, the ligature of the arteries was now practised and succeeded in Germany by P. Hahnemann, in England by Wismann, and in Prussia by Dieffenbach. Many, however, continued to do the wound was large, and supplicated long and profusely; the healing was slow; the ends of the bone protruded, and, growing far beyond the soft parts, required the cure so long, that the patient was not infrequently worn out. Hence the best surgeons began seriously to consider what further could be done, with a view of lessening the exposed surface of the wound, and making a better covering of bone for the ends of the bone.

According to Sprengel, most of the old surgeons preserved a flap of flesh, and he is therefore by no means disposed to reject our countrymen, Lowdians, as the authors of this method, though it is acknowledged that the latter surgeons' practice was never introduced on the flap was formed by making an oblique incision through the aneurysms from below upwards. — See James Yonge's *Curios Transactio* et *Veritas*, 4to. Lond. 1678; and Sprengel's *Gelehrte Art. Chirurg.* 1, 1, p. 408.

Thus, if Sprengel means that many of the old surgeons endeavoured to preserve a partial covering of flesh for the bone, there can be no fault or loss of correctness; because we find, that they drew back the flesh before they divided it, and Celsius and some others ran did more, for, after cutting down to the bone, they detached the flesh further from it spirally, previously to taking the bone; but, on the contrary, if Sprengel wishes us to believe, that these were practitioners who, previously to Lowdian, in the operation of amputation formed what in England is usually understood by a flap, that is, a portion of flesh, possibly of a semicircular shape, and saved particularly from one side of the incision for covering the bone, I cannot see any reason for excluding with Sprengel's observation. Upon the merit of Lowdian's experiment, and the practice and principles as related by J. Yonge, were reflections lately sent me by Mr. Christopher I think with great pleasure, as perhaps he is right in thinking that the third edition of this work did not do justice to the accuracy of the latter writer.

"At the time Yonge wrote 1678," says Mr. Christopher, "it was supposed impossible to heal a mass before the bone had solidified, and therefore no surgeon would venture upon an attempt at making the surface to the best advantage. Now this truth by the first intention was the chief object of Mr. Yonge in proposing the flap operation, and it is to be seen, not only in Mr. Ainslie, who wrote precisely half a century after him, but in the numerous authors of this improvement. It is related in a letter addressed to his friend Thomas Jones, Esq., in London, dated Plymouth, Aug. 10, 1775, and published 1779, at the end of his *Curios Transactio* et *Veritas*. It begins thus:

"Sir, I find by yours that you are satisfied with the instrument I gave you, of a way of amputating large vessels, so as to be able to cure them yet without any other wound; and without losing or scaling the bone. It is a manner which I will now advise to you to be a little after I have first taken notice of what you desire, that there is a necessity of scaling

the ends of those bones left bare after the usual manner of amputating; before the stump can be exactly cured; that you never yet found it otherwise, so that when it had been attempted, the masses have spontaneously, and the cure came off thereby."

Yonge then acknowledges, that it was from an ingenious Doctor, Mr. C. Lowdian of Exeter, that he had the first hint thereof. He then describes the operation—the laying down the flap over the face of the mass, and sewing it by four or five stitches, &c. After this, Yonge proceeds without methoded measurement of the advantages of this mode of operating over all others then in use, viz. that it is more speedy—the cure not occupying a fourth of the usual time—no suppuration—no inflammation—no danger of metastasis—no liable to break open again from slight injury—and lastly, much better adapted to the patient from an artificial leg, &c.

The foregoing account will show says Mr. Christopher, how far Mr. O'Halloran's method, presently to be described, in which he divides the flap and the stump as distinct surfaces, can be regarded as a revival of Lowdian's operation, or whether it has been suggested or improved upon by the mechanical ingenuity of the Irish and French surgeons—the advocates of M. de la Faye and Vachon appear to have been merely envious and malicious spectators for the suppression of foreignness. Gargrave's opinion had also for its object to supersede the use of the flaps, which, however, after twelve years' practice, he was obliged to give up, and the second author has laid down the flap, the particulars of all these methods the reader will presently meet with. Therefore, therefore, founded upon the practice of those gentlemen, I venture, saying fairly is admitted as evidence against the day-operation of Lowdians, which nevertheless appears sinking in the estimation of the best modern surgeons; perhaps for various advantages is gained by it over the common mode of operating in the lower extremities, as now practised—but even here does not mean where we are glad to resort to it: a few years since, I attended a patient in consultation with a friend at Danvers, in Essex, where we thought it necessary to remove a large leg for a cancer of the tibia. An incision in front extended so high, that no integument could be saved, and the limb would have been remained above the knee, if I had not suggested the propriety of making a flap from the side of the leg. The tibia was obliged to be saved as high as possible, but the flap was left sufficiently long to cover the surface, and that most important object, the head of the knee, was preserved, to bear the pressure of a wooden leg. In the removal of the arm at the shoulder-joint, doubtless the advantages of making a flap from the distal are sufficiently established, but in the mode of dressing, I perceive that an English surgeon will admit, that the practice of M. Larrey (perhaps the most eminent surgeon that has been formed by the wars of Bonaparte, and whose practice will be beneficially noticed in the sequel) the method of Yonge or Lowdian, who wrote 14 years before him! Larrey introduces flaps to break the flap to prevent tension by the first intention! Lowdian's object is simply to lay the flap over the wound to prevent eversion, and to keep the surface "per se appressed" in those vessels."—To the correctness of these statements of Mr. Christopher, I believe that every impartial surgeon will bear witness; and it is very far from me to think him for his slight commendation, and say, that I have commonly looked over the copy of the *Curios Transactio* et *Veritas*, preserved in the valuable library of the Medical and Chirurgical Society, and find, that what he has stated is fully confirmed by the contents of that ancient work. At the same time, I retain the belief, that the example set by Mr. Ainslie, with respect to the proper method of dressing stumps and obtaining a speedy union of the wound, is entitled to the praise of posterity; because his advice was so well executed that it soon produced a revolution in practice, while the correct suggestions of Lowdian and Yonge, like the hair in Othello of the double incision, had sunk into oblivion, or were only known to a few adherents of surgical antiquity.

As Sprengel remarks, Pottius, Biondi (*Opera* d'Opera de Chir. p. 441), De la Voisignie (*Tratt. Chir.* 2da Ediz. 1804, p. 231), and most other surgeons of the seventeenth century, contained the author of first drawing up the integuments, and then

applying a band round the member. Heals also took particular pains to recommend the ligature of the vessels, and expressed a strong aversion to the actual cautery. Neither did he express an aversion to the knee joint, because he thought that the joints, which must be left behind, would impede the healing of the stump, and he was apprehensive of the artificial surface of the lower extremity discolored. He la Verugnon relied upon the astringent properties of nitric acid, and he praised drawing back the muscles by means of the kind of ligament by Fabrice's filigree.

Taking off the limbs at the joints was first recommended again in another time by J. Mercurio, who was more partial to styptics than the ligature; and he drawing the wound employed compressed styptic powder.—*Chirurgia*, p. 181.

Mansueti de la Mothe adopted the plan of operating recommended by Divius; he was also one of the first who made common use of the ligatures in operations, afterwards drawing out the vessels with the forceps and tying them.—*Trattato Chirurgico*, de Chiar. vol. 2, p. 111. Lousiana's original suggestion of amputating with a flap has been briefly noticed. About eighteen years after Vesalius's publication, Peter Verduin, an excellent surgeon at Amsterdam, referred to the judgment of the professors a new kind of flap-operation, which he had put in practice.—*See His Recueil des Nord Américains*, de la Chirurgie, tom. 2, p. 100. The following are the chief particulars of Verduin's flap-operation.

Two compresses were applied, one under the heart, and the other on the course of the large vessels. The thigh was wrapped in a fine linen cloth, which was sustained by some turns of a roller. The operation was covered with a piece of leather, six inches broad, furnished with three straps with buckles, so secure it round the part. The instrument was placed in the usual manner. The part above the place intended to be amputated was supported with a leather strap. The joint of a crooked knife, which was made to pass as near as the back part of the bones as possible, was thrust in on one side of the leg, and made to come out on the other. The knife was then carried down nearly to the tendo achillis, and thus a septum across the whole calf of the leg. The flap being formed, the operation was finished in the ordinary manner. The wound was then washed with a wet sponge, in order to clear it from the fragments of sawed bone. The leather strap, which served to secure the flaps, was next loosened, and the flap laid over the stump. The wound was dressed with hydropic, salt, and rose, over which was put a cushion, sustained by strips of sticking-plaster. Upon this cushion was placed an instrument called a retentorium, consisting of a compress, and a spongy roller, which were made to press upon the stump, by means of two straps, which crossed each other and were attached to the broad leather strap surrounding the thigh.

In 1760, Robinson, an able surgeon at Geneva, gave an account of Verduin's practice in the Royal Academy of Sciences, which, however, declined to pronounce any judgment about it, without further experience.

Though this method of amputation was adopted by de Couding, in a tract published at Amsterdam in 1760, it was afterward slightly extended by P. Marquet, an account of the operation with which Robinson failed, the society with which the flap served for the support of the lower extremity, and the avoidance of stiffness by the non-exposure of the bone. He also drew upon the economy of the stump, for the application of an artificial foot.—*De l'Amputation d'un membre*, 8vo. Paris, 1760. He also disapproved of the flap-operation, because it appeared to him that the irritation of the bone by the pressing instrument was in itself powerful inflammation; he pointed himself after the manner of Heister, and was strongly in favor of the use of ligatures.

Some excellent prospects were delivered by J. L. Petit concerning amputation. He expressed the disapproval, and instead of the flap-proposed amputation knife formerly employed, first because (who use the straight instrument) cannot know with sharp knives, how soon the ends of the bone separate, because such bones are cut, and are exposed to the air, and the rest of the body. He proved that making the

dissect in the superficial parts was frequently followed by hemorrhage; and for the suppression of bleeding he thought it the best principle to promote the formation of a coagulum.—*Opus de l'Art de la Chirurgie*, an 1750, p. 100. See Hemorrhage. For compressing the vessels, he employed an instrument which covered the stump like Vesalius's retentorium, and made pressure by means of a screw. The only objection to Verduin's method was, that the extension of pressure to the bone frequently induced the formation of so huge a flap. He laid down the suitable general manner of always removing as much bone, and as little flesh, as possible; he which purpose, he intended what he termed the double incision, or dividing the thickness of the stump through the soft parts into two stumps. About an inch higher than the place where he meant to saw through the bones, he first made the superior cut through the integuments down to the tendons; the flap was then pulled up as in lesser the flesh corresponded to the extent of an inch, and the saw was then now divided at the highest point of that extremity. Lastly, the flesh was left out of the way with a scissor, and the bone was sawed through high enough up to allow of its extremity being well covered with flesh and integuments. The greatest defect in the doctrine of Petit, relative to amputation, was the condition he put in practice, instead of the ligature.—*Yeast des Malades*, Chap. vol. 2, p. 100. The first performance of amputation at the shoulder-joint, by de Prost, and the improvements and alterations of that operation suggested by Goussier, de la Faye, Desault, &c. I shall notice in a future series.

In chronological order, the next most celebrated method is the history of amputation, was the promulgation of an opinion by T. H. Goussier, that Verduin's flap-operation might be turned back to times of great antiquity, the method described by Celsus being very similar.—*Histor. Med. Chap. vol. 6, p. 181*. On this point, with reference to Lousiana, the true inventor of the flap-operation, I have already delivered my own sentiments.

The flap-operation of the leg, after Verduin's manner, was tried by de la Faye, who found that the pressure of the flap was not strong to check bleeding from the vessels, as it only operated on the anterior tibial artery, and by pressing the bone more firmly against the rest of the bones, he thought was risk of mortification threat to be commenced.

Verduin and Robinson, as we have seen, made only one flap. Two French surgeons, Ravaton and Verduin, afterward thought that it would be better to have a flap from each side of the limb. They were also advocates for tying the vessels, and ligging the two flaps also closed, so as to prevent their speedy union, and further suppurations and profuse suppuration.

However, there is some difference in their methods of forming the flaps. Ravaton, who suggested the plan to the French Academy in 1726, made three deep incisions down to the bone; first, a circular one, with a crooked knife, within four finger-breadths of the bone intended to be removed; and then with a somewhat larger knife, the two little perpendicular ones at the first, one at the first part, and the other at the back of the thigh; and, having care not to touch the principal vessels, he detached the two flaps from the bone.

Verduin formed the superior flaps in two incisions. After applying the saw, you he extended the part with two roll thumbs, at the distance of one finger-breadth from each other, was in the bones where the bone was to be divided, the other on the side where the thickness of the flaps were to be formed. He then drew almost a four-finger-width of the bone, as the first part of the flaps, and it must be noted the circumstance, so that it might come out at the opposite part; then, directing the edge of the knife along the bone, he saw down to the superior third, where he separated the first flap, which, as the author says, makes a round or conical figure at its extremity. The second flap was made in a similar way on the inferior side of the bone.—*Trattato del Furore d'Armen*, 4. two par. Ravaton, 8vo. Paris, 1726. De la Faye, in 1734, de l'Art de l'Art, 1. 1. 2. ed. 1734. Verduin, *His. de Chir. 8vo. Marseille*, 1757.

In presence of M. Quinquy, Garagaud performed the flap-operation according to the method of Verduin and Desault. We know that they made no operation on the vessels, and that their intention was, that the

flap, when applied to the stump, and sustained by a protruding apparatus, should evince antiseptic healing.

Garrigue's patient died on the third day after the operation; hæmorrhage having had a considerable share in producing death.

The simplicity of machines described by Verbiest, La Foye, &c. had no other guiding than of keeping the flap near the surface of the vessels, so as to compress and close them. In consequence of the difficulty of making this compression previously required, the most considerable hæmorrhage occurred between the two flaps, and when cut, generally hæmorrhage retarded, Garrigue decreased in desire to employ ligatures.

With these views, two years after the foregoing case, Garrigue performed a flap-operation on the arm, preserving two flaps, according to the method recommended to the Academy by Roux. The brachial artery was tied, and the patient was cured, without any embarrassment.

Garrigue made a third trial of this operation on a soldier dangerously wounded in the right foot by the trampling of a horse, which fractured the upper part of the two bones of the leg, and several of the toes: the patient recovered in fifteen or twenty days.

In this operation the single flap was made. Garrigue was fatal, however, that the single flap might create some difficulty in maintaining the ligatures, and he therefore took a review of ligatures, and where they were situated; but of this objectionable plan I shall not speak. He rightly performed dressing and bandaging the stump to the use of the compressing machines devised by Verbiest and La Foye; and his choice of a straight knife, instead of a hooked one, was equally judicious.

The preceding case dictated a truth, which will last as long as surgery survives, that it is advantageous to apply the ligatures in such manner as to produce as more than the result, so that they may fall off the wound, and the parts move quickly into.—M. de Garrigue, in *Mémoires de l'Académie de Chir.* t. 3, p. 136m.

At one time, an objection frequently made against the foregoing method was, that when the foot cut off was immediately laid over the stump, inflammation and abscesses were apt to occur. Roux, in 1765, Dr. Hunter O'Halloran, a surgeon at Limerick, was led to make the experiment of detaching laying down the flap till the end of the ten or twelve days after the operation, when it was conjectured that the risk of inflammation and abscesses would be decreased. The result of O'Halloran's book is apparently corroborated by the facts brought forward. Here we see one of the grand plans, raised upon by one worthy countryman, James Young, viz. the choice of an amputation of the wound from laying down the flap without delay, whereby it grows up, and because the wound could not always be healed without separation, it was determined that it never should do so. However, it is unnecessary to say, that O'Halloran's suggestions were given only in the theory, and not in the practice of surgery.

Alexander Morris, senior, was an open opponent of various methods which originated among the French surgeons, and, as you are clear, he disapproved of the compression; he secured the vessels with ladders and ligatures, and was the inventor of a machine, which has been extensively applied under the name of Morris's roller.—*Medical Essays of Edinburgh*, vol. 1, p. 337.

Goodell, like La Foye, retained amputation as a first choice, and he did not amputate, as previously, as shortly as possible, in every case of gunshot, much less in every instance of a cold cutting or virus. From a passage quoted I have just from Dr. Boon's *Cyclopædia*, it would seem that this mode was known to the ancients; yet, according to general opinion, and I cannot give than it is incorrect from any passage in the *Præceptorum*, it is recorded as being in the first instance, which was employed this very useful instrument.—*Ann. Chir. et Obs.* vol. 1, p. 411, 5th Ed. 1774.

About the year 1778, the removal of limbs without bloodletting was a subject of good deal trouble. A single case recorded by Séguin, which, when mortified, was removed without hæmorrhage, was the foundation of the scheme. The arteries were completely tied up, and the parts removed.—(*Fluxus*, *Med. Chir.* vol. 3, p. 165.) A similar occurrence was related by Akerl (*Ann. Medica*, p. 337); and Labatier proposed himself a believer in the necessity of bloodletting

stage, on account of the vessels being filled with coagula, and therefore he also proposed of tying and tying the vessels, or rather tied off, without bloodletting.—(*Fluxus*, *Med. Chir.* vol. 3, p. 272.)

In cases where the preceding basis of the stump was affected with necrosis, Bismar, an experienced military surgeon, visited to describe a second time, and urged a variety of operations in defence of the principle.—*Mém. de l'Académie de Chir.* t. 2, p. 254. He associated with Le Boon and Bismar, however, about the propriety of restricting amputation to very cases, and has stated numerous examples of limbs being saved, which, according to the doctrine then in vogue, would have been cut off.—(*Revue Médicale de Chir.* de l'Académie, Paris, 1786.)

M. Louis, a French surgeon of extraordinary talents, introduced the plan of dividing the loose muscles first, and tying those which are closely connected with the bone. He showed that the muscles of the thigh, after being divided, were retracted to an unusual degree. He observed that the superficial ones retracted along the tract, more or less obliquely, without being attached to the bone, were drawn up with greater force, and to a greater degree than others, which are deeply seated, in some instances, parallel to the axis of the femur, and draw to this line throughout their whole length. The situation begins, the very instant when the muscles are cut, and is not completed till a short time has elapsed. Hence, the effect should be prompt, and be as perfect as possible, before the bones moved. In the amputation of the thigh, Mr. Louis was always desirous of letting the muscles contract as far as they could, and for this reason he was rather averse to using the tourniquet, as the greater pressure of this instrument in some measure counteracted what he wished to take place; and hence, at one time he preferred letting an assistant make pressure on the artery, though he subsequently expressed his approbation of the tourniquet proposed by M. Eschsch for compressing the femoral artery.—*Mém. de l'Académie de Chir.* vol. 1, p. 60, 61.

Animated by such principles, Louis reached a kind of double process, different from that of Hunter and Pott, and different also from Almon's method, which I shall hereafter name. By the first stroke he cut, at the same time, both the integuments and the loose superficial muscles; by the second, he divided those muscles which are deep and closely connected to the bone. On the first deep circular cut being completed, Louis used to remove a band which was placed round the limb, above the track of the knife. This was taken off in order to allow the divided muscles to become retracted without any impediment. He next cut the deep adherent muscles on a level with the surface of the bone, which had been divided in the first incision, and which had now attained their utmost state of contraction. In this way he could evidently see the bone very high up, and the perfect division of the skin from the muscles was avoided. Louis was conscious that there was more necessity for seeing inside than skin; and he knew that when an incision was made at once down to the bone, the retraction of the divided muscles always left the edges of the skin projecting a considerable way beyond them. Hence he derived the plan of first seeing a portion of skin by dividing it from the muscles and turning it up, quite unnecessary. As the bone should always be viewed rather higher than the division of the soft parts, Louis, like J. L. Pott, and most other judicious surgeons, highly approved of the employment of a tourniquet. He was likewise the author of some valuable instructions for preventing the pressure of the bone after the operation.—(*Ann. Médec. de l'Académie de Chir.* t. 2, p. 258—410, 411.) The important reader, who takes an interest in reading the remarks on amputation published by this greatest of all the French surgeons of the last century, with the exception perhaps of J. L. Pott and Bismar, will be interested at once with the force and perspicuity of his language, and with the correct propriety of a good deal of the practice he has laid down.

In England, Cheselden, and not J. L. Pott, is regarded as the surgeon who revised Hunter's method, by proposing to divide the soft parts by a double incision, that is, by cutting the skin and dividing the muscles first, and then, by dividing the muscles down to the bone, as a last with the edge of the bone, so that the bone might be saved higher up, and its end as more com-

ply covered with skin. Whether Cheselden had the priority in this improvement, I cannot presume to say; but it is rare as a record if it is Gaillier's, introduced by Duret's thesis on the operation, as early as 1783, which was long prior to the appearance of Pott's posthumous writings; and Mr. Cheselden further remarks, that during his apprenticeship to Mr. Fenn he had communicated to that gentleman his sentiments about the double incision.

It is only to render the flaps free, avoiding a pyramidal or star-shaped shape, which sometimes happened notwithstanding every improvement or talismanic incision; a circular bandage was employed, which acted by supporting the skin and muscles, and preventing their retraction. This bandage, when properly applied, from the upper part of the limb descended, fulfilled in 4 or 5 turns, sometimes the roll proposed, though quite strong yet carried out very lightly. Mr. Sharp was indebted, therefore, to reserve the ancient plan of bringing the edges of the skin together with sutures; but the pain and other inconveniences of this method were such, that it was never extensively adopted, and Mr. Sharp himself abandoned it. The same bandage, however, which he used to put over the end of the artery, remains in fashion even at the present day.—(Treatise on the Oper. p. 216. Clinical Inquiry, p. 268.) It is to be regretted that an excellent modern surgeon, the late Mr. Day, should have contemned so much as he had done the use of sutures, in bringing together the edges of the wound after amputation.—(Practical Observations on Surgery, p. 284, edit. 2.)

In opposition to Lenoir, the insufficiency of his method for preventing the protrusion of the bone was asserted by Valentin, who thought the wound ought to be left exposed by dividing the parts while they were in a state of tension; for which purpose he recommended changing the position of the limb, according to the parts which he was about to cut.—(Recherches Critiques sur la Chirurgie Moderne, 2^e An. 1778.) Valentin's proposal seems never to have made much impression on the profession; whether on account of its inconvenience or inefficiency, I know not, certain it is, least cases present themselves, in which the position of a limb absolutely cannot be changed during the operation, owing to the nature of the disease, or cannot be altered without extreme agony.

At this period arose the celebrated controversy about the propriety of amputation in general. As Sympson remarks, several French surgeons now began to be cautious, with De Bist and Biquet, that the operation was crueler on the sight, grovelling, and in particular that many had complained of tenderness might be cured without amputation. Such was the doctrine of Boucher (Mémoires de l'Académie de Chir. t. 2, p. 284). Germain (Anfangsgr. der Wundkunst, 8vo. Götting. 1755), and Pott—*Memoires sur les amputations* de Pott de l'Ac. de Chir. vol. 1, p. 230. The latter especially argued the production of delay in gun-shot wounds, and commented severely on the losses. But the writer who at this time made the most noise in the world by his general condemnation of amputation, was Bagnard (Mémoires de Médecine Amputatoire, 8vo. Paris, 1781), whose sentiments received a complete refutation from his own contemporaries. Pott (Chir. Works, vol. 2, Mémoire d'opérations de Chir. t. 1, p. 221), and de La Martinière (Mémoires de l'Académie de Chir. vol. 8, p. 1), and also three later writers, in whose reference will be made in speaking of Gun-shot Wounds. Even Bagnard himself was compelled to admit the necessity of amputation in cases of gangrene.—*Annales des Sciences Médicales*, 8, 178.

Bagnard's collector, the celebrated Schenckler, inclined to the same doctrine, and has detailed several cases, where limbs were not only shattered, but actually carried away by balls; yet where a cure followed without amputation. One of his maxims was, that it was better for the member to be taken off by gun-shot than by the surgeon's knife, as the ball opened on a healthy subject, and the knife on a person debilitated by an hospital.—*Chir. Works*, 3^e édit. 1, p. 203. In a little volume ready on this subject, he contradicted himself by shattered limbs without any gangrene. His mode of operating was that of M. Lenoir. He described post-operation on the hip and shoulder; but recommended those of the knee and elbow as better amputating.—(Voyage Schenckler, 3^e édit. 1, p. 2.)

Soon after the middle of the last century, the prac-

tice of amputating at the joints began to excite increased attention; but as this is a topic to which I must presently return, it is unnecessary now to dwell upon it. The writings of Pott, Wodan, Wodan, Bransler, Bismet, Sauter, Park, Moreau, and Vespaucière, in relation to this subject, deserve particular notice.

I now come to Mr. Alanson, whose name is an conspicuous in the history of amputation, as that of any surgeon yet mentioned. His chief objects were to hinder a protrusion of the bone, and to promote union by the first intention. He rejected the band which was formerly put round the limb for the guidance of the knife, as it interfered with the action of the muscles, and the contraction of the circular incision through the skin. When the ligament had been applied, an assistant grasped the amputations with both hands, and drew them and the bones directly upwards. The operator then fixed his eye upon the proper part where he was to begin the incision, which was made with considerable facility and dispatch, the knife moving with greater quickness in consequence of the loose state of the integuments.

After the incision through the skin had been made, the assistant still continued a steady support of the parts, while Mr. Alanson separated the cellular and ligamentous attachments with the point of his knife till so much skin had been drawn up as would, with the muscles divided in the particular way he desired recommended, fully cover the whole surface of the wound. Thus, instead of applying the knife close to the edge of the integuments, and dividing the muscles in a circular perpendicular manner down to the bone, Mr. Alanson proceeded as follows: when standing upon the thigh, and standing on the outside of the limb, he applied the edge of his knife under the edge of the supported integuments, upon the inner margin of the various internal vessels, and cut obliquely through them and the adjacent muscles upwards as to the limb, and down to the bone, so as to lay it bare about three or four finger-breadths before then it was usually done by the common perpendicular circular incision. He then drew the knife towards himself, then keeping its point upon the bone, and the edge in the same oblique line already pointed out for the former incision, he divided the rest of the incision in the same direction as round the limb; the point of the knife being in contact with and revolving round the bone through the whole of the dissection.

According to Mr. Alanson, the speedy cessation of the above-directed incision will be much expedited by one assistant continuing a firm and steady elevation of the parts, and another taking care to keep the skin from being wounded as the knife goes through the muscles, at the outer part of the limb. Mr. Alanson cures the old method of depriving the bone of its periosteum to a considerable extent above and below the part where the saw was to pass, not only as creating unnecessary delay, but, since the periosteum serves to support the vessels in their passage to the bone, as apt to produce exsanguination above the part where the bone is to be divided with the saw. Instead of this practice he recommended first the application of the retracter, as advised by Cooper and Hennenrich; and then dividing the bone at the part where the saw is to pass, whereby the bone may be sawed off faster than is usually practised; a material object for hindering a protrusion of the bone and forming a sound cicatrix.

If the flesh of a stump formed in the thigh agreeably to the foregoing plan, he gently brought forwards after the operation, and the surface of the wound as then viewed, it may be said to resemble in some degree a radial cleft, the apex of which is in the extremity of the bone; and the parts thus divided Mr. Alanson thought the best calculated to prevent a singular stump.

The part where the bone is to be laid bare, whether two, three, or four finger-breadths higher than the edge of the retracted integuments; or, in other words, the quantity of muscular substance to be taken out is making the double incision, must be regulated by considering the length of the limb, and the quantity of skin that has been previously moved by dividing the circumference attachments. The quantity of skin saved, and retractor suitable taken out, must be in such exact proportion to each other, that the whole surface of the wound will afterward be easily covered, and the limb not more shortened than is necessary to elude the saw.

After the removal of the limb, Mr. Alanson drew each

bleeding every artery cut with the same force, and tied it as tightly as possible with a common slender ligature. When the large vessels had been tied, the torn edges were immediately slackened, and the wound well cleaned, in order to expose any vessel that might otherwise have remained concealed with its orifice blocked up with coagulated blood; and before the wound was divided, its whole surface was smeared with the greatest quantity of lint, by which means Mr. Alcock frequently observed a pulsation where the hæmorrhage previously appeared, and turned out a small clot of blood from within the orifice of a considerable artery. He is very particular in recommending every vessel to be secured that is likely to bleed in the attack of the sympathetic fever; for, besides the fatigue and pain to which such an accident immediately exposes the patient, it seriously obstructs the desired union of the wound. He used always to dress the whole surface of the wound with a sponge and warm water, as he thought that the lubricity of any coagulated blood would be a considerable obstruction to the quick union of the parts.

The skin and muscles were now partly brought together; a flannel roller was put around the body, and several towels or three pieces of flannel were placed over the upper part of the thigh, so as to form a firm support to the limb, when the Alcock called a sufficient bandage, which he usually added to the support of the skin and muscles. The roller was then continued down in a circular direction to the extremity of the stump, not so tight as to press rudely on the skin, but so as to give an easy support to the parts.

The skin and muscles were now placed even the lower in such a direction that the wound appeared only as a line across the face of the stump, with the edges at each side, from which points the ligatures were left out, so that usually no other ligatures were given. The skin was gently secured in this position by long strips of linen by that of the breadth of about two fingers, spread with cotton or any cooling ointment. If the skin did not easily meet, stripes of melting plaster were pasted. These were applied from below upwards, across the face of the stump, and over them a soft tow-padded, and composed of linen, the whole being retained with the many-tailed bandage, and two tails placed perpendicularly, in order to retain the dressing upon the face of the stump.

Mr. Alcock continued the plan of raising the end of the stump far from the surface of the bed with pillows, so the patient usually reclined by it; and he considered it best to raise the stump only about half a finger's breadth from the surface of the bed, by which means the muscles were put in a more relaxed position. The many-tailed bandage Mr. Alcock found much more convenient than the wisp of cotton, especially used in former times to support the dressing; and he observes, that though this seems well calculated to answer that purpose, yet if it be not put on with particular care, the skin is liable to be drawn backwards from the face of the stump; nor can this would be found wrong, providing upon the stump is removed. (See Alcock's Pract. Diss. on Amputation, 8vo. Lond. 1774.)

The chief peculiarity of Alcock's method of operating, namely, the mode in which he recommended the incision of the muscles to be performed, did not, however, meet with universal approbation, and his extensive dissection of the skin from the muscles was considered as excessively painful. The formation of a correct wound by following Alcock's directions, was regarded by several as impracticable. (See Martin's Puerperia, &c. 1, s. 88; Loder's Surgery, &c. 1, s. 7; Wardlaw's, 8vo. 2d ed. 1815, p. 51; Ruy, Anatomie, vol. 7; Goussier, Nouveau, &c. p. 5; Ruy, Pract. Med.) In any system there can be no doubt of the truth of some of the criticisms made by these and some other writers on the impossibility of performing a wound with a regular circular cavity, by following the directions given by Alcock; for if the knife be turned round the number of half-circles required, certainly upwards towards the toes, it will pain greatly, and of course the end of the incision will be considerably higher than the beginning. But though Alcock probably never did himself exactly what he has stated, I am sure that his possession of making an oblique division of the muscles all round the member has been the source of great improvement in amputations in general, and is what is actually used in by all the best modern surgeons. It is true they do not actually per-

form the oblique incision all round the limb by one stroke or rotation of the knife round the bone, as Alcock says that he did; but they accomplish their purpose by repeated, distinct, and suitable applications of the edge of the instrument turned obliquely upwards towards the bone or bones.

Among others, Myer failed fast with some of Alcock's instructions, and thought every dissection might become equally attended by using skin enough, and then cutting through the tendons. The first incision, however, he directed obliquely upwards through the integuments, while they were drawn up by an assistant, and he then cut down to the bone. (Pract. Theoretique d'Amputation, 2vo. Bernay, 1783.) Several consider Myer's plan merely as a revival of Galien's method, as it had in view only the preservation of skin, and not the formation of a fleshy cushion. (Goussier, Nouveau, &c. 1, s. 105.)

Kirkland endeavored to improve Myer's plan by cutting off a piece of skin at each angle of the stump, so as to keep the integuments from being drawn into folds, and in opposition to him, he collected the writings of Hippocrates concerning the successful treatment of deep-seated sores without amputation. (On the present State of Surgery, p. 573, and Thoughts on Amputation, 8vo. Lond. 1798.)

B. Bell used to operate very much in the same way as Myer; and when it seemed advantageous to make a flap, he did not disapprove of the plan suggested by Ruyss, Vesalius, and Alcock. (Hist. of Surgery, &c.)

An interesting paper on amputation from some years ago published by Loder; its chief purport was to defend Alcock's method with some slight modifications. (Clar. and Medic. Biblioth. 1793, p. 59, 2vo. 1794.) However, the alterations suggested by Loder do not seem to Goussier at all adequate to the removal of the difficulties with which the mode of raising the flaps exactly after Alcock's directions is attended. (Nouveau Traité de l'Art. de l'Amputation, Goussier, p. 4, 4to. Bernay, 1812.)

The removal of flaps, without bloodless, proposed by Goussier at Calais in the 14th century, has met with warm adherents in J. Wiersebe and W. G. Ponsquet. J. Wiersebe, was a ligature, which was daily made tighter, took off an are above the elbow. In the disease he applied a styptic powder. On the fourth day, the flaps were removed down to the bone, which was secured with a cloth. (Goussier's essay, 8vo. Bernay, 1812.) Ponsquet thought the plan suited to excruciating rapid subjects, but he well adapted to the leg or forearm. (Von der Verringerung des Gliedes, 8vo. Gießen, 1798.)

Some other modes of doing flap-amputations, and in particular the suggestions and improvements made by Her, Chopart, Dupuytren, Larrey, Lisfranc, and other modern practitioners, will be noticed in the description of the amputation of particular members. In the mean time, I shall conclude this section with mentioning the feasible attempts made at different periods to render the patient less sensible of the agony produced by the removal of a limb.

Theodorus, as we have said, administered for this purpose opium and henbane, and though he was assisted by many of the ancient surgeons, few surgeons have denied the practice worthy of being continued. Goussier made the experiment of saturating the pain with a light opium; but a machine devised a few years ago in England expressly for the object of stupifying the nerves of a limb previously to amputation, is perhaps not undeserving of further consideration. (See J. Moore's Method of preventing an Amputation Pain in severe Operations of Surgery, 8vo. Lond. 1784.) The great reason of the latter plan being given up is, that even patients have made more complaint of the sufferings occasioned by the process of making the anæsthetic of the nerves than of the agony of amputation itself without any such expedient. Yet daily experience proves that the pressure caused on the sensitive nerve by sitting with the limb in a certain position, will completely destroy the feel and feel, and this with such an absence of pain, that the pressure applied is easily abstracted of the patient being asleep, as it is termed, used to this to walk. On the little good done by warming and flapping the stump, Lisfranc, a method once much recommended (I read and heard after the Amputation of the Osella and the Warner, p. 3-25, Leipzig, 1806), I am sure it is unnecessary for me to comment.

AMPUTATION OF THE THIGH.

The thigh might always be amputated so low as the disease will allow, so that as little of the bone may be cut off as possible, the pain may not be greater than necessary, and the section of the wound have not so great an extent as would otherwise happen.—(Lancet, Med. Obs. p. 256, t. 3, ed. 1.) The patient is to be placed on a firm table, with his back properly supported by pillows and assistants, who are also to hold the limbs, and keep him from turning too much during the operation. The side of the sound limb is to be fixed by means of a strong band, or rather to the distal leg of the table.

Then, however, through an imprudent mistake to obtain the above advantages, let the surgeon ever be successful of the great action as stopped operations, that all the diseased parts should be removed, but it is to be a result of the truth of what I have said, that it is more reasonable to cut away too much than too little.—(Norton, in the *Advancing practitioner*, p. 50.) At the same time, I do not agree with some modern writers, who deem it necessary to separate beyond the limits of every abscess and tumor, which may not only be far above a diseased joint of diseased fracture. Many of these operations are only like ordinary abscesses, and do not go well after the main disease or injury is removed, as I have often seen. Where it is a reasonable rule to cut off a limb above every reflection of swelling, sometimes two or six inches above of the thigh would be sufficient, thus, circumstances immediately demands, and the greater distance of a limb than a less operation would be considered. However, in all cases where the bone is supposed to be removed, or the muscles are affected with the vascular changes peculiar to hyperæmia or disease of the circulation, the operation should be performed sufficiently high to take away all the diseased parts. In extraordinary operations, where there has been much suppuration in the limb, and a crisis runs up, Mr. Guthrie says, that if the tubes extend only a short way between the muscles, the wound being it may be divided with; but if the matter has been upon the bone, then will have to open the bone, and amputation should be done high enough to remove the affected part of it.—(The *Lancet*, Wounds, p. 62.)

Many writers disapprove of amputating too close to the knee (Guthrie, Op. p. 60; and Langenbeck upon one objection to it not specified by us) other author, viz. that if the operation be done lower down than two inches higher above the knee, the femoral artery strikes the aponeurotic sheath, which it here receives from the brachio-vascular and thoracic, and cannot be drawn out with the forceps, so as to be securely tied, without first slitting up the sheath. Hence, he recommends cutting through the muscles at the distance above the knee already mentioned.—(Ed. *Med. Clar.* t. 1, p. 571, 2nd. Ed. 1850.) But when I come to look at the breadth of two adult hands, and see how thick of the limb would be situated at all points, only to see a little muscle, I cannot bring my mind to concur with Langenbeck—the artery being more than the sheath cut.

The next thing is the application of the tourniquet.—(See *Tourniquet*.) The pad should be placed exactly over the femoral artery in its bed, a cushion as low as conveniently done. When the thigh is to be amputated high up, it is better to let an assistant compress the femoral artery in the groin with my compound instrument, furnished with a round elastic cord, calculated for making direct pressure on the vessel without injuring the surrounding parts. Some authors would give a strong preference to this method, whereas the thigh is amputated high up or low down.—(Guthrie, *Principles of Med.* p. 155. Brown, *Principles of Med.* p. 256. See also *Langenbeck's Op.* in *Ed. Med. and Surg. Journal*, 20, p. 43.) Were the patient, however, in a delirious state, and unable to bear loss of blood, or pain, or in this way, or some considerable bleeding, by means of the compression with the instrument of the internal dissection, I should feel disposed to employ the tourniquet. Alas! however, circumstances would admit of its application. In instances of the thigh, the great objection to the use of the instrument is, that it impedes the flow and impedes the return of the same arteries after they have been cut; the consequence of which is, that the surgeon cannot make so high an in-

ter-vascular could do the Cooper's method which are more fixed and attached to the bone. Yet in order to have the same well carried with force, and no danger of a sugar-loaf stump, the latter object is one of the importance. Perhaps the best general rule is to attempt the application of the tourniquet in amputations done as high as the middle of the thigh, except where the patient is exceedingly weak, so that he cannot bear the smallest loss of blood, and no strong intelligent assistant is at hand, to whom the compression of the artery in the groin can be judiciously confined. When, however, the operation is to be done much higher up, or where the employment of a tourniquet is wisely avoidable.

Whether the right or left thigh is to be removed, it is customary for the operator to stand on the patient's right side. The great advantage of this position seems to be, that the surgeon's left hand can be then more conveniently and quickly brought into use than if he were obliged to stand on the same side as the part he is about to amputate. This seems to be directly assignable reason for this habit; for when the left thigh is to be amputated, it is certainly more inconvenient to have the right hand between the operator and the foot, than it is to be removed. But this is found true in most cases not having the left hand near the wound.

Mr. Guthrie, in speaking of amputations on the two lower thirds of the thigh, observes, that "in these cases the tourniquet should be used," but in operations high up the thigh, he joins all other surgeons in recommending the internal artery to be compressed against the os pubis.—(See *Ed. Med. and Surg. Journal*, p. 152.) The utility of slackening the tourniquet completely, however, as soon as the principal vessels are severed, a piece of advice delivered by this excellent surgeon, I perceive, enters to right on the position which he specifies, viz. the impediment made by the strap of the instrument to the rotation of the muscles, and the consequent difficulty in such operations of turning the bone, because in common practice the bone is always moved before any of the vessels are secured; and loosening the tourniquet entirely, when any arterial branches still require the ligature, must certainly be objectionable, if loss of blood be a disadvantage. In these operations high up the limb, indeed, where the arteries are sometimes tied, before the division of the bone, the employment of a tourniquet at all is quite out of the question.

We know that it was my opinion of the late Mr. J. Bell, that the first of blood through a large artery could not be completely stopped by pressure; and the late Mr. Hey adopted a similar notion, in consequence of seeing a case in which the operation of two tourniquets in the thigh did not restrain the hemorrhage from a fungus hæmorrhoides of the limb. He says, the pressure of the tourniquet does not completely obstruct the passage of blood in the arteries; it only diminishes so much of the force of the current as to enable the vessels, in a second stage, to resist their natural contractile power so effectively as to prevent hemorrhage.—(See *Hey's Pract. Obs.* p. 157, 158, ed. 2.) Of the uncertainty of this doctrine no man can doubt, who sees the femoral artery with its open mouth on the face of a stump not bleeding, while the tourniquet is tight, or should pressure be kept up, but throwing out the blood to a great distance the instant the pressure is discontinued. Nor, I suppose, can any surgeon, who has attended to the circulation, and seen how completely pressure overflows the flow of blood through the spirit-stemmed artery-artery, just in the situation of John Bell and Hey take any particular pause. Here I can speak with confidence, because I have myself attended at the amputation, and assisted at this operation several times, and feared the consequences of the preceding writers partially and almost completely. Were any further testimony required, I might cite that of Dr. Hunter, who remarks, among other things, that in a suppurated case, operation upon by Mr. Pott, the vessel of blood cut from the principal artery was so much that the quantity contained between the point of pressure and the point of incision, through the vessel.—(*Principles of Military Surgery*, p. 157, ed. 2.) The same has happened twice in the example, where I actually opened the blood in a press pressure.

Mr. Hunter, in talking of the pressure, the preceding instance, observing that pressure suggests nothing but only to stop the pulsation of an artery in a limb,

but also to arrest completely the flow of blood, can be easily applied by pressure of the fingers only. And, in order to prove the correctness of this remark, he has occasionally, when on going about with him at hand, compressed both the femoral and iliacal arteries with the fingers of one hand, while with the other hand he has saved the limb, and this, as he affirms, with the arm or even less than that of his hand (followed the artificial mode). His constant pressure, however, is so in the pressure to be made by an assistant, and to employ an instrument.—See Ed. Med. and Surg. Journ. vol. 55, p. 351.

If, then, the flow of blood through an artery can easily be controlled by pressure, how can we so explain the occasional occurrence of bleeding notwithstanding the pressure of one, or even two, tourniquets? Without doubt, by the fact that the parts of these instruments, when not duly arranged, do more harm than good, by raising the level of the vessel, and perhaps also, in Mr. Day's conception, by the additional compression, that increases of the fragile blood-vessels and include a large quantity of blood, and with blood pressure, and for a considerable time, after the main supply of blood to them is cut off. The same thing happens in the disease called aneurism by anastomosis, as I have had several opportunities of witnessing, but in aneurism there is always that in the vessel, when some time after Mr. Hodgson had told the story, and after articles, Mr. Lawrence divided away part of the finger, exposing the artery and bone, and yet a considerable bleeding went on from the farther side of the wound.—(See Med. Chir. Trans. vol. 9, p. 216.)

The application of the tourniquet is generally left too much to assistants; but, as far as my judgment extends, no operator is justified in commencing the operation before he has examined, and fully satisfied himself that the tourniquet is correctly applied. Mr. Guthrie correctly tells us that he never lost an artery, in consequence of hemorrhage during the operation, although the tourniquet was in the charge of a surgeon of ability; and the advice with which he follows this statement is worth recording: "In a case of this kind, where if the tourniquet is raised at all too soon, the surgeon should not continue twisting and turning it, while the patient is bleeding, but cut it altogether, and compress the artery against the bone." This remark, I think, cannot be too highly commended.

The shape and size of the part of the tourniquet employed are of importance. At St. Bartholomew's, the pads employed are very firm, being composed of wood, or cork covered with leather, and rather thicker than the thumb, the upper surface being flat, and the lower, which is put under the thigh, being convex. They are about as thick and a half an inch long. A dark pale-ash-wood extremely well, as I can attest from the observation of some hundreds of amputations in that hospital. A convex form firmly was the regular form of pads which were too large and soft, and not palmately shaped. As Mr. C. Bartholomew remarks, the principal objection is a large pad, that the bottom of the tourniquet is so much raised by it, that a considerable space is left on each side of it, where an compression is made on the limb, however closely the tourniquet may be applied, and that there will be a risk of hemorrhage from such vessels as happen to be in these situations. The same gentleman also is of opinion it is not better than a finger, and gives it simply over the artery, so as to prevent the possibility of dislocation.—(Pract. Obs. in Surgery, p. 11—12.) Mr. Hildreth says, "The pad should be first and rather square, and steadily kept steady over the artery, while the ends of the bandage in which it is contained, are placed on the limb. The strap of the tourniquet is then to be put round the limb, the instrument being brought directly over the pad, thus the artery is free. The strap is then to be drawn tight, and buckled on the outside, with a pressure to griping, and not interfere with the artery, which is to be turned out, and pressure is sufficiently furnished over the circulation. If the artery is to be turned out, the strap is not sufficiently tight, if the pad has not been well applied, and they must be repeated."—The Glasgow Wounds, p. 204.

In two amputations at St. Bartholomew's Hospital, I saw the tourniquet with its pads and parts had been washed, and as the case of these was a good deal of

blood was lost, because another tourniquet happened not to be in the room, and pressure on the artery in the groin was not immediately adopted. I coincide with such writers as recommended the rule of always having two tourniquets ready. Guthrie even goes so far as to advise putting both of them round the limb before the operation commences. Nor does the Abbé's primary tourniquet, p. 58, cut the frequency of a tourniquet breaking is not so great. However, as I demand wide pressure, and the plan would be very objectionable in large amputations, where it is a material advantage to have plenty of room between the place of the incision and the band which goes round the limb.

An assistant, after grasping the thigh with both hands, is to draw up the skin and muscles, while the surgeon, beginning with that part of the edge of the limb which is towards the femur, makes a circular incision as quickly as possible, through the integuments down to the fascia, on, as Mr. Guthrie and Dr. Hennen recommend, even completely through it. According to Mr. Guthrie, the skin cannot be sufficiently removed, unless the fascia be divided, which he appears to think ought rather to be drawn up with the integuments than dissected from them.—(On Gunshot Wounds, p. 235. Also Hennen's Military Surgery, p. 202.) On the contrary, Professor Larnach is very particular in exposing the artery to avoid cutting through the fascia by the first sweep of the knife, because he holds that the arteries are better held together, and can be more regularly divided, by cutting them and the fascia at the same time.—Ed. for the Chir. b. 1, p. 551.

Nor does M. Roux divide the fascia by the first sweep.—(Note, see in Spanish immediate de la mano apply Amputation circulaire, p. 3, Bro. Paris 1814.) At St. Bartholomew's, the surgeon rarely or never cut through the fascia with the integuments, but saw at carrying the knife perfectly down to it all round the limb. This, of course, could be done without fear of doing rather more; for, as Guthrie observes, if the outer layers of the muscle be torn and there a little tension, this causes less pain than the additional strokes of the knife for dividing any portion of the skin and cellular substance not completely cut through in the first instance. Guthrie also dissent from Myerson and others, who are advocates for cutting the skin obliquely instead of perpendicularly, because he holds the first edge of the integuments thus separated from the subjacent cellular membrane, very apt to slough.—Nor does the AM. Grosser's (Glasgow, p. 101.) At a slight ordinary amputation, the first incision should be made four inches below where it is intended to saw the bone. When the thigh is left, the large amputation knife will be found the best. Before beginning this first cut, the arm is to be carried under the limb, till the knife reaches almost round to the side on which the operation stands. With one sweep penetrating at least to the bone, the knife is then to be brought round to the point where it first touched the skin. Thus, the wound is more likely to be regularly made, than by cutting first on one side, and then on the other, while the patient is under some degree of pain, in consequence of the interrupted quivering with which the incision is made. At the same time, I ought to remark, that the late Sir C. Bland, and some other surgeons, whom I have never known, used to complete the circle by two strokes of the knife as well and expeditiously, that their constant attachment to this plan could hardly be traced fault with.

The next object is the preservation of as much skin as will afterwards, comply with the incision, cut in an oblique direction, nearly the end of the stump with the utmost facility. It is rather difficult to lay down any other general principles for the guidance of the surgeon in making amputations. I am disposed to agree with several modern writers, that the painful dissection of the skin with the incision has been overestimated and promised to a very unnecessary extent, that is to say, unnecessary if the division of the muscles be performed in the most advantageous manner. Guthrie, one of the best surgeons at Paris, does not dissect the skin from the muscles as he is separating the thigh, but takes care, after making the necessary incision, to leave the integuments and subjacent flesh very freely drawn up before commencing the dissection of the muscles. This instruction is also strongly advised to be done uniformly and steadily, as noted

the member, but in dividing the muscles any irregular projection of the skin interferes with the regularity of the incision of the bone.—(Northern Brit. Med. Assoc. Transactions, p. 103.) Instead of dissecting back the skin, Desjardins cuts all the old parts at once in the bone, which he real reserves, after retracing the muscles.—*Synopsis*, in *Edinb. Med. and Surg. Journal*, vol. 14, p. 202. However, Langenbeck, another of the most skilled operators on the continent, professes dividing the integuments from the fascia by about two diagonal incisions (Edinb. Med. and Surg. Journal, 1855, p. 561), as is perhaps the most common practice in the London hospitals. Some late writers, particularly Mr. Byrne, in expressing their preference for incision as a means for the end of the bone, seem to forget one fact which I have often noticed, viz. that the muscular cushion, though at first thick and good, soon settles to a comparatively level state.—This is common in a general way in the animal economy, prevailing whenever the natural action of a surface is lost or prevented. So Audley Cooper states, that the covering for the end of the bone made by integuments and not vessels; for if vessels were preserved with the integuments they will contract, and retraction of the skin covering the stump will be the result.—*Lancet*, vol. 1, p. 144. Desjardins also thinks skin a better and more durable covering for the end of the bone than muscular fibres, which after a time become scarce; and hence he compares the quantity of integuments which ought to be saved, by the measure of the circumference and diameter of the member. Thus, when the limb is nine inches in its circumference, the diameter is seven inches; therefore, two inches and a half of skin on each side is to be saved.—*Edinb. Med. and Surg. Journal*, p. 75. But this author cuts the muscles perpendicularly, so that the bone is left to separate much more skin from the flesh than is necessary when the incision through the integuments is carried obliquely upwards. Mr. Hey's method of calculation, which I shall presently notice, appears more adapted to ordinary practice; and he says, "the division of the posterior muscle may be begun at half an inch, and that of the anterior at three quarters, above the place where the integuments were divided."—(Pract. Obs. in Surgery, p. 525, ed. 5.) With the view of preventing the necessity of dissecting the skin from the fascia, Mr. Galtius, as already noticed, surrounds the place of cutting through the fascia, together with the integuments, by the first stroke of the knife, and retracting these parts in the same way, instead of dissecting them free with a scalpel. If this method be found perfectly efficient, and it is not objectionable, as expressing the opinion to be cut unecessarily, I think the reason specified against it by Langenbeck, and explained in a preceding page, not strongly enough to form a just ground for rejecting a procedure which comes with the almost advantage of preventing the necessity for all painful dissection of the skin from the muscles. However, in secondary operations of the thigh, if the integuments be unscathed and will not retract, Mr. Galtius appears of their being dissected back to an equal distance all round.—(On Gun-shot Wounds, p. 205—206.) Dr. Bennett, by giving an oblique direction to all the incisions through the muscles, diminishes the necessity for much dissection of the integuments, and he says that in a small limb he has repeatedly performed the operation with oversight of the knife, cutting obliquely upwards and upwards at right angles to the bone.—*Principles of Military Surgery*, p. 250, ed. 2. The writer, like Mr. Galtius, also recommends carrying the knife through the fascia in the first circular incision; and so does Mr. C. Buzhasson, who makes no mention of dissecting back the skin, but simply states, that the "integuments and fascia being divided by a circular incision, and retracted upwards as high as is judged necessary, the superficial muscles should next be divided."—*Ann.—Pract. Obs. in Surgery*, p. 21, Nov. 1855. We are therefore so positive, that the joint Galtius and others is, dividing the separation of the skin from the fascia unecessarily. My own observations in practice lead me to believe, that the dissection of the integuments from the subjacent parts need formerly to be carried to an extent beyond all reasonable necessity, and that, as it has now passed, proceeding, and finally by leaving a large loose pocket for the judgment of nature, it ought to be abandoned by every surgeon, who follows the method of carrying the bone considerably higher than the first cut through

the superficial vessels. I am not, however, prepared to assert, that no one has or all is generally disposed to, but my mind is disposed to follow the procedure adopted by Mr. Hey, as recommended by Mr. Hey, the great advocate. This gentleman, who Desjardins (Edinb. Med. and Surg. Journal, 1855, p. 561), is an advocate for operating with a single incision, and for preserving such a quantity of muscular flesh and integuments as are proportionate to the diameter of the limb. By a single incision, he means first an incision through the integuments above; secondly, an incision through all the muscles, made somewhat higher than that through the integuments; and finally, a smaller incision through this part of the muscular flesh which adheres to the bone, made round that point of the bone where the saw is to be applied. The proportion of these incisions from each other, he says, must be determined by the thickness of the limb and which the operation is to be performed, making allowance for the contraction of the integuments, and of those muscles which are not adherent to the bone. Supposing the circumference of the limb to be twelve inches where the bone is to be divided, the diameter is about four inches, and if no retraction of the integuments were to take place, a sufficient covering of the stump would be afforded by making the first incision at the distance of two inches from the place where the bone is to be saved, that is, at the distance of the semi-diameter of the limb on each side. But as the integuments, when in a normal state, always recede after they are divided, it is useful to make some allowance for this recession; and to make the first incision in this case at least two inches and a half to three inches before the place where the bone is to be saved. As the posterior muscles of the thigh retract a great deal after the process of healing, Mr. Hey advises this incision to be begun half an inch above the place where the integuments were cut, and the anterior recedes three quarters of an inch. The integuments may be well secured in the back above and below the place where they were divided; for the distance from that place must be computed from the mark laid upon the surface of the muscles in dividing the integuments. Thus, in fact, in a common thigh amputation, Mr. Hey deemed it necessary to divide the skin from the muscles merely to the extent of half an inch at the back part of the limb, and of three quarters in front; a very different practice from the old custom of making quite a long of integuments, and leaving these back as the upper piece of a glove is turned down, or pulled as the sleeve of a coat are turned up.

In common operations of the thigh, there strongly disapproves of separating the skin from the muscles, as a conservative highly unfavourable to the healing of the wound by adhesion; he divides only a few of the collateral bands between the integuments and muscle, and occasionally he has retained M. Leds in cutting through the skin and superficial vessels, saying—

"More vie la Résection de la Tige avec l'Amputation," &c. p. 9.

I believe the generality of the late modern operators are now convinced of the impropriety of dividing the muscles exactly in the manner directed by Mr. Atkinson, viz. by leaving the bone recede unecessarily all round the bone, with the edge turned obliquely upwards towards the point where it is intended to apply the saw. It is a logic, indeed, to which I have already called the reader's attention in the foregoing remarks. Langenbeck says, that he is perfectly convinced of the impossibility of forming a circular wound with one stroke of a large supporting knife, and joins Mr. Hey in approving of the triple incision.—(Edinb. Med. and Surg. Journal, 1855, p. 561.) The objections are urged by Wardlaw against Atkinson's method are mathematically correct, inasmuch as the centre of the edge of the knife, in this gentleman's method, must be equal, and the end of the incision be considerably higher than the beginning of it. Such must be the result of performing the division of the muscles all round the limb by one continued stroke of the knife, with its edge directed obliquely upwards; for the idea of moving the knife reverse in this manner while its point is confined to its regular, regular, downward curve on the bone, I believe, is not abandoned as so really practicable. Yet with the exception of Desjardins, who confined himself to the triple incision conducted on the principles of M. Louis (Edinb. Med. and Surg. Journal, 1855, p. 561), few experienced surgeons follow so acknowledged, that in this operation the

the advantage does proceed from the oblique division of the muscles, the benefit of bringing which method into practice Mr. Adams justly and judiciously doubts, however he may have erred in recommending the circular method to be tried with an amputation of the knee. Nor are there many living surgeons who entertain a doubt of the excellence of the principle advocated by M. Louis in meeting the ends of dividing the lower extremities. First, and then such as are deeper and adherent to the bone. In fact, a combination of this last method with the oblique division of the muscles, not exactly by one but several strokes of the knife, constitutes the mode of amputating at present most extensively adopted, and sometimes termed, as already mentioned, *amputation à la triple incision*. Thus, after the skin is cut, and as much of it as is required and would be as deemed necessary, the operator runs through the lower muscles of the thigh at the edge of the remaining skin, first those on the inner part of the thigh, and then those as are situated behind. For this purpose he makes two or three strokes of the knife, as may be found necessary, carefully directing them, slightly upwards towards the point where he means to raise the bone. The oblique division of the muscles does not merely enable the operator to raise the bone higher up than he could otherwise do, and hence at the same time more secure for covering its extremity, but it is a preservation of sound, uncontracted muscular fibres, which inevitably form the most efficient and durable covering to the stump. It is this without precisely coinciding with Blandin's plan, and, trusting entirely to skin for covering his stump, makes an essential detachment of it from the aponeurosis, and then only straight down to the bone. The latter muscle is merely cut through near its end considerably, leaving those which are deeper and attached to the bone in a condition to be cut higher up than could have been previously done. Lastly, there are also to be divided with the edge of the knife directed obliquely upwards or towards the place where the bone is to be raised. Some operators do more than this; for, after cutting down to the bone, they follow the plan of Volpe, and detach the flesh from its whole circumference gradually with a scalpel, in the extent of about another inch, in order to be enabled to raise the bone still higher up. "Inter osseum et cutem partes integritate scalpula, cito et cum ad os, reliquas ab eo infra cutem, et infra os subscindam, ut de *capsula parte* aliq. distans amputetur." This method, I think, deserves commendation, because it may have considerable effect in lessening a protrusion of the bone, if it does not, in conjunction with the foregoing method of operating and judicious dressings, render this disagreeable event quite impossible. As long as I live, however, I shall never forget a poor soldier, whose thigh had been amputated at Remond-Zoom, and who was brought about ten days after the operation into the military hospital at Orléans, under my care. Not the slightest union of any part of the wound had taken place; abscesses had formed under the flaps on every side of the stump; the loose skin was literally a large bag of putrid matter; the muscles were wasted to almost nothing, and their tendons retracted and shrinking still farther away from the extremity of the bone, which projected at least three inches beyond the rest of the part. This unfortunate man had been attacked with chronic leucorrhoea soon after the operation, and probably it was in the discharge of the stump by the effects of this disease, and in the strong, uncontracted tendency of the muscles to retract themselves, induced by this state of the system, the deplorable state of the stump was to be attributed. He survived nearly a fortnight in the hospital before he died; preferring to which almost large abscesses, communicating with the bottom of the stump, attended the whole use of the patient. As I had every reason to believe that the operation had been skilfully done, perhaps when I saw that the above mode of amputating will make a protrusion of the bone impossible, it seems scarcely possible, as the witnesses may sometimes originate from causes which are quite independent of the particular way in which the operation has been executed.

The practice of discharging the bone from the circumference first in the state of stump, and after the other principal measures are completed, as advised by Crisp and Leroy, I have sometimes seen done at St. Bartholomew's Hospital, and have practised myself on

other occasions, with the decided advantage of letting the bone be raised higher up than could otherwise have been effected. Mr. Guthrie, after the incision down to the bone, even recommends drawing back the muscles from it "at the space of two or three inches, on the side of the limb, or other circumstances may require." But I should be reluctant myself to admit the practice to this extent, though inclined to think most favourably of it within more moderate limits. If no more than three inches of the member be between the first circular cut in the skin and the place where the knife strikes at the bone, and then raise away two or three inches more of the flaps, it is clear that in many examples we should be getting very high up the limb, and if a small part of the muscles from the bone to the extent of two or three inches were thus raised, it would in all events be of no service unless the bone would adhere to being raised at this point distant from the termination of muscular division of the muscles. However, if this were truly practicable, in cases which I have mentioned to yourself, it would certainly be very useful to the accident-prone man, and even by A. L. Petit, that in amputations as high as the bone and so little of the flesh should be taken away as possible.—(*Tratado de Med. Chir. 3, p. 132*). When this kind of amputation of the thigh has been from the bone adopted, certainly, as Mr. Adams says, should be done always to divide the thick aponeurosis covering the femur in the lower part.—(*Mem. sur le Remond à la Paine après l'Amputation, p. 134*).

With respect to Blandin's method of separating the thigh by a vertical incision, already mentioned, he recommends raising the skin obliquely upwards quite unnecessary a few lines back, in order through the muscles, layer after layer, with the precaution of separating the first striated fibres he divides the second; the latter will then cut through on a level with the first that had been previously raised and separated, and so on down to the bone. This, says he, is the right way of forming a free hollow cone, of which the integuments, which were drawn up before the muscles were cut, form the base, from which we gradually contained the various layers of *adiposa*, and the highest part of which is the bone itself. Blandin owns, that this method is sometimes tedious and painful, but in his opinion, those advantages are more than counterbalanced by the benefit procured for the patient.—(*Revue Chir. de Douai par Richer, t. 2, p. 567*).

All the muscular fibres, on every side, having been cut down to the bone, a piece of linen, somewhat broader than the diameter of the vessel, should be torn to one end, along its middle part, to the extent of about eight or ten inches. This is called a retractor, and is used by placing the exposed part of the bone in the slit, and drawing the end of the linen upwards on each side of the stump. In this manner, the retractor will steadily keep every part of the surface of the wound out of the way of the saw. "Grady thinks that in amputations of parts, where there is only one bone, the outer portion of the linen should always be applied over the anterior muscles, as these ought essentially to be most evenly kept back, so that no portions of them may interfere with the action of the saw."—(*Norman sur de l'Amputation par Grady, p. 110*). This is a preference, however, which may not be of great importance, though I confess that there appears some reason to think Grady is right. This meritless surprise, J. L. Petit, whose name I always mention with pleasure, strongly commands the use of the retractor, the ends of which he drew over the anterior muscles; he says that he has employed this simple and useful means, but that it did not end the bone of every body, especially of those who consider all the work of an operation is caused in the question of its performance, as he thinks it unnecessary reasoning to say, this is the true way.—(*Tratado de Med. Chir. 3, p. 132*). I have seen the bone do much mischief in consequence of the operator neglecting to use the retractor, but my conscience obliges me to remove such surprises as might be derived from the use of this simple contrivance. There are some who have rejected the use of the retractor, because they have not it put under the neck of the saw, and observe the action of the instrument; but this very circumstance added against the retractor is, when considered, the strongest one that could possibly be brought forward in its favour, as the surface of the wound itself, and particularly the edges

of the skin, would, in all probability, suffer the same fate as the bone, by getting under the teeth of the saw, if an operator were employed, in attempting to cut the bone high up, as closely as possible to the soft parts. I think no one can then say that these frictional objections to the use of the peritonæum, and I know that many who have been with myself are witnesses of the practical frequency done by the saw in amputations, are deeply impressed with its utility to the object of this language. I have often seen the soft parts skillfully divided, and I have, in these same instances, seen the operators directly adjacent to the saw all the while, which every one was ready to believe, by their usually sitting through one-half of the ends of the flanges together with the bone. Men with liberal feelings are to enter a sigh, not to let a given be lost, at their previous asseverations, but now had their presence more excited than they by themselves, the possible means. But because defending the surface of the saw from the teeth of the saw, the operator will undoubtedly avoid the operator to save the bone higher up than he could otherwise do.

Mr. Lister, of Edinburgh, endeavors to state, that the saw is the only necessary thing in the case of amputating instruments; and he adds (adding, as I suppose, to amputations at the joints), that it was seldom required that might be supposed; and as particularly occupies all kinds of amputation apparatus. Here it should be remembered, that the gentleman's practice is that of disarticulation, so which he gives the internal peritonæum; a method in which undoubtedly the peritonæum may be divided with, as, while the saw is acting, one or both of the flaps can be effectively held out of the way by an assistant. The same principle also explains, in some instances, the surgeon's rejection of the instrument, the application of which is so convenient in certain disarticulations. (See *Edinburgh Med. and Surg. Journ.* vol. 28, p. 43—44.) Here, however, I am trusting amputations by the circular incision, as which practice I consider best the instrument, and the operator too, would be commonly recommended.

Another proceeding, which seems fit for regulation, and which, indeed, Mr. Alcock very properly condemned, is the practice of scraping up the peritonæum with the knife, as far as the muscles will allow. Nothing seems more probable, than that this way is the cause of the excruciating pains which necessarily happen after amputations. At all events, it is a cruel, needless measure; as a sharp saw, such as ought to be employed, will never be expected to go slower than the bone as the peritonæum. All this the operator ought to do is, to take care to cut completely down to the bone all round its circumference. Thus a circular division of the peritonæum will be made, and upon this point strikes the saw should be played. This is the method which was approved of by J. L. Petit. (Treatise on the Saw, &c. p. 108.) If it were I have always done and recommended; yet it must be confessed, this difference of opinion prevails about the necessity and fitness of dividing the peritonæum. Gracile, in coming with several others, entertains considerable apprehensions of the effects of the peritonæum being torn and lacerated by the saw, excruciations of the bone and muscles up to the point being possible consequences of the high operation and inflammation of this membrane. Hence he is an advocate for making a circular cut through of the place where the saw is to be applied, and then scraping away all below that point as the flange descends. (Norman for the Am. practitioner, p. 166 and 167.) Perhaps no very great objection may be against this mode, which is not necessarily followed, though I have some doubts of its utility, as it seems seems preferable is the habit of the having of least to hit with the saw the precise point at which the remains of the peritonæum remains; and in confirmation of the utility of Petit's practice. Mr. Gracile's experience may be added, who says, "I have often moved through the bone, without previously touching the peritonæum, and the excruciations have been lessened, and with its little inconvenience to any others." (On Gun-shot Wounds, p. 165.) A very modern author, impressed, like every other, with the fear of tearing the peritonæum with the saw, differs from them, in thinking it best to cover the peritonæum, especially by which means, he says, that at least half as much of this membrane, and a very

portable quantity of muscular flesh, may be preserved for covering the end of the bone, inasmuch as the muscular fibres adherent to the peritonæum will remain contained within; an advantage which this practice secures very important while the edge of the bone is sharp. Inasmuch as the bone, by covering the method highly useful, as the sharp edge of the bone may be not nearly covered with it, but peritonæum and the cellular membrane contained with it, thereby the adoption of this practice, to secure as this book has set a very long time and may occasion of the skin, and some other protection of the bone of a strong. (Edinburgh Med. and Surg. Journ. vol. 28, p. 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

that in no part of the operation of amputation do operators in general display more awkwardness, than in scraping the bone, though, if we except directing the saw against the flesh, the facts are here less pernicious in their consequences than the effects already named. At the time of scraping the bone, much depends upon the assistant who holds the saw. If he elevates the lower portion of the thigh bone too much, the saw becomes obstructed that it cannot work. On the other hand, if he allows the weight of the bone to operate too much, the thigh bone breaks before it is nearly sawed through, and its extremity is splintered. It is one of the most common remarks of such persons as are in the habit of frequently seeing amputations, that the part of these operations, which a plain carpenter would do well, fails the skill of a commoner surgeon, and few operators begin themselves well in the management of the saw. Many of them begin the action of the instrument by moving it in a direction contrary to the inclination of its teeth. Many, seemingly through confusion, endeavor to shorten this part of the operation, by making short, very rapid, and almost convulsive strokes with the saw. Almost all operators fall into the error of bearing too heavily on the instrument. The operator will now best, who makes the first strokes of the saw by applying its head to the bone, and drawing the instrument across the part towards himself, so as to make a slight groove in the bone, which serves very materially to steady the future operations of the instrument; and who makes long regular sweeps with the saw, rather slowly than quickly, rather lightly than heavily. But there is often a slight in the construction of the new steel, which impedes its action, quite independently of anything on the part of the surgeon. I allude to the edge of the instrument not being a little broader than its blade. When the saw is well made, the work always makes plenty of space for the movement of the rest of the instrument. The instrument, as Mr. Gracile recommends, should cut with both edges, backward and forward, which expedites the operation, and what is of more consequence helps to prevent splintering when the bone is nearly divided, because the division can be finished by the backward stroke, which are the most gentle. (On Gun-shot Wounds, p. 165.) Gracile commends the plan of using the saw, for the purpose of facilitating its action (Norman for the Am. practitioner, p. 165.) and though the method is incorrect enough, the best operators in this respect do not consider it sufficiently important for adoption. If the bone should happen to break before the sawing is finished, the sharp-pointed, projecting spicule, thus produced, may be removed by means of a strong, cutting sort of forceps, termed bone-spreaders. The perpendicular division of the bone, across a sharp edge at the extremity of its circumference. It is not the common practice to make any allowance for the removal of such sharpness; yet Gracile recommends doing it away (Op. cit. p. 165), and Mr. C. Hutchinson makes it an invariable rule, whether there be any occasion to use the bone-spreaders or not, "to take off the splinters, and scrape or rub down the saw so as to round the sharp cut edge of the bone with a mouse bone scalp, in order to prevent the soft parts from being lacerated.

were brought over the end of the bone, in fitting the stump.—*Pract. Obs. in Surgery*, p. 54. Though I have not followed this practice, or rather the part of it which relates to setting off the edge of the bone, as soon as adapted to lesions in amputation of the thigh, I know of no objection to it, unless it be on the score of its feasibility, and the other without occasion. All preceding points of bone, it is the ordinary custom to remove.

After the removal of the flesh, the femoral artery is to be immediately closed with a pair of forceps, and tied with a firm round small ligature, the knot being tied kind which is recommended and used by my friend Mr. Lawrence.—(See Ligature.) Care is to be taken to turn the accompanying lymphatics of the anastomosing vessel out of the wound. Now if the removed limb ought to be tied, though the ligature should not be placed round the artery, just where it emerges from its adventitious sheath. The late Mr. Hey was inclined to tie the femoral artery twice, leaving a small space between the ligatures. Some reasons against this plan will be found in the article Hemorrhage. The other arteries are merely taken up with a thread. After tying as many vessels as require it, one-half of each ligature is to be cut off towards the knot on the surface of the stump. One portion is quite sufficient for withdrawing the ligature when that becomes loose, and the other being only an unnecessary bulk, and productive of irritation and suppuration, should never be allowed to remain.

My friend, the late Dr. Herman, in his excellent publication, justifies the improvement of removing one-half of the ligature to Mr. James Vesich, a minor surgeon, who, in April, 1808, published some valuable precepts relative to the mode of tying the arterial in amputation.—(*See Esch. Med. and Surgical Journal*, vol. 2, p. 176.) But highly as Lawrence of the error of the anonymous paper here referred to, it is impossible for me to suppose Mr. Vesich could be the first, or modify the first, who suggested such improvement.—When I visited an apprentice to St. Bartholomew's Hospital, in 1775, an surgeon of that hospital ever followed any other mode, and the practice was then so far from being new there, that practitioners who were at the hospital seven years before myself, had sent one-half of each ligature regularly cut off the first time they went into the operating theatre of that magnificent institution. The use of very broad ligatures, and the inclination of a considerable quantity of flesh in the wound, together with the vessels, were also practices quite exploded at St. Bartholomew's at the very beginning of my apprenticeship. Mr. Vesich, however, seems to merit the honour of having been perhaps the first to see the example of tying every vessel, the Professor, as well as another attending, with a single silk thread, taking care to include, as far as was possible, round the artery; and when this had been done, he took off one-half of each ligature, as well as possible in the knot, "so that the future matter absorbed was a mere rind, exposed much what I had seen answered to me."—(*Esch. Med. and Surg. Journ* vol. 2, p. 176.) The use of a single silk thread, therefore, was the part of these improvements, probably originating with Mr. Vesich, though the principles which led to his innovation were unquestionably first suggested by Dr. Jones.

Mr. Adams directs the ends of the ligatures to be left hanging out at the two extremities of the wound according as their nature may point out at last. But when a ligature is situated in two wounds of the wound, it is best to bring it out between the strips of absorbent plaster, at the lowest part of the surface, afterwards extending across one-half the wound to put it under angle, would cross a great deal of useless erythematous and suppuration. The advantages of this method of placing the ends of the ligatures were well explained by Mr. Vesich. In his practice, the the direction of cutting off the half of each ligature, has been common in the London hospitals, and at St. Bartholomew's in particular, many years since, I presume, that this was believed to be the practice; since it has been frequently adopted in those institutions ever since 1795 as I can testify from my own personal observation. These remarks are offered without the slightest intention of disputing from the views of the above-mentioned paper, which to repeat with valuable effect, nor am I influenced by any design of throwing

loss on the history or character of any other individual at the expense of Mr. Vesich, being at the same time unacquainted with the exact periods when either this improvement, or that of removing the half of each ligature, commenced. Mr. Ross is one of the few reasoning modern surgeons who declare their preference to the method of bringing out all the ligatures at the lower angle of the wound; the benefit of having them brought out thus low, so as to keep up a drain for the day just that they first being in the position greater than that of arranging them in the points of the wound nearest to them.—*Mém. sur la Résection de la Humerus* (Arch. p. 25.)

As Mr. Herman observes, the following are the admirable rate and order of ligatures, the separating the threads of which they were composed, and placing them at convenient points along the line of the artery, or vessel, and the actual removal of one-half of each ligature, were improvements very closely made;—1807 says he, "an improvement which appears to me of great consequence, was the last of interference, and is now the source of adoption, although the artery once secured, and the value of adhering duly acknowledged, it is the most obvious of all." I allude to the plan of removing the ends of the ligatures altogether, and then leaving it to extensive wound the greatest possible chance of immediate union." The first printed mention of this practice, as far as Dr. Herman's investigations have discovered, was in a letter written by Mr. Haire, dated Southampton, Essex, Nov. 1795. "The ligatures," says this gentleman, "sometimes become troublesome and retarded the cure. An intimate friend of mine, a surgeon of great abilities, proposed to cut the ends of them off close to the knot, and thus leave them to themselves. By following this plan we have seen strange issues in the course of six days. The blood ligatures thus cut in consequence made its way out by a small opening in a short time without any trouble, or the patient being sensible of pain."—(*See Esch. Med. Journ*, vol. 2. Certainly, considering the backwardness of the surgeons of the method, as Dr. Herman remarks, is very satisfactory.—*Principles of Military Surgery*, p. 116, ed. 2. In a letter received by me from Mr. Haire, surgeon at Southampton, and dated June 2, 1819, he tells me, "My predecessor, Mr. J. Wilson, the late purser of Mr. Haire, suggested a fresh in 1795 or 1796, and cut off the ligatures close to the arteries, and so to be avoided. He followed the recommendation of Mr. Haire, who had sent some of the method practised on the continent." In September, 1812, Dr. Herman, who was serving with the army in Spain, taught the adoption of this plan, which, he expected, would not only prove useful in preventing immediate union, but in avoiding any accidental violence to the arteries, and the wrong interference of the younger doctors in trying to cut them away. Between September and January, thirty-four cases were treated in this way without any consequences following, or the small particles of silk left behind giving rise to any apparent irritation. Dr. Herman also mentioned to me 3. Mr. Greer, some of the small circles of silk, a part of which had come away with the dressing, while others had shewn out on opening the silk particles, which formed over the face of the stump at the place where the arteries had been tied. Some few of the ligatures never made their appearance, and the patients complained of no uneasiness whatever. Observed by the staff of the method, Dr. Herman afterward published an account of it.—(*See Esch. Med. Repository*, vol. 2, p. 175, and vol. 5, p. 261.) This gentleman subsequently feared that Dr. Maxwell of Bradford had adopted the plan as far back as 1798; and Mr. Fortescue, who was at Stockton during the period of Ayrton, was also then followed by some of the surgeons of that city, without any ill effects.—(*Hercules Military Surgery*, p. 175-176, ed. 2.) In July, 1814, Mr. Lawrence communicated to the Medical and Chirurgical Society of London, seven cases and observations highly in favour of the method, and the proceedings which he lay each stress upon as being for the purpose of making firm incisions, composed of what is called Vesich's silk.—(*See Esch. Med. Journ*, vol. 9, p. 176.) And in a paper of later date, he says, his former opinions had confirmed the necessity of the method, "that this plan, by destroying irritation and inflammation, and simplifying the process of dressing, was anti-

fully protects the comfort of the patient, and the success of the surgery, which it has not produced in consequence of any unpleasant effect, in the cases which have come under his own observation." According to Mr. Lawrence, the small knots of silk generally were very early, and came away with the discharge; that when the integuments have united by the first intention, the ligatures often came out rather later, were very indolent suppurations, and that, in some instances, they remain quietly in the part.—*Mem. vol. vi. p. 5, 6, 7.*

After the case of Wounds, it occurred to me to send to Mr. Collier and to myself, though our ligatures were certainly not so intricate and elastic as those employed by my friend Mr. Lawrence, whose plan essentially requires the use of elastic ligatures made of double silk. As I found two aprons the first after the case, and was therefore obliged to wear my patients at three days to the use of the elastic, I lost the opportunity of witnessing the effects of this method. The next Mr. Collier I attended himself, and the new plan and the method were applied to his patients. It seemed almost equally well; with the exception that we did not use the smallest ligatures, which he regarded as indispensable. When the plan is tried, single among threads and silk, or under the kind of regularity which will be described in some place (see *Lectures*), there is no supposition, for otherwise, the knots would be large, and liable to cause suppuration and future trouble. The method has likewise been tried by Dr. Keen on Staphylococci, but it is not explained whether he used single threads or silk, or whether any improvement resulted from the method.—*See Bulletin de la Société des Sciences en 1844, on Paralytic de la Chaire d'Anatomie de la Clinique Française par P. J. B. vol. 1, p. 112.* Yet, another surgeon has to state, that the method is not generally adopted, and that one of the best writers, as I shall hereafter mention (see *Hesperides*), has noticed a case and some experiments which are unfavorable to the practice.—*Ibid.*, in *Ann. Med. Chir.*, vol. 7, p. 155. By Mr. Astley Cooper, the practice has been stated as abandoned, and he has himself given it up.—*Lancet*, vol. 1, p. 118. Mr. Keen, in two of these instances, has also some sort of looking elsewhere than from the presence of the knot of ligature, though he approves of the plan when the wound will not unite by the first intention, which, however, can hardly be known beforehand.—*On Gunshot Wounds*, p. 301. On this subject, a more particular attention, that no case can be regarded as the trial of Mr. Lawrence's method, unless properly such ligatures as he himself employs be used.

Dr. Koch, Professor of University Surgery at the University of Munich, Bavaria, after performing the operation on the thigh, contents himself with approximating the flaps without securing any vessel; that is, he keeps the flaps together, as he finds them keeping the cut surfaces in perfect co-aposition is sufficient to prevent hemorrhage, and his success has been truly surprising. Dr. Wagner has long since been in this country, that ligatures may be dispensed with in cases of gunshot wounds, in which they are not only applied by most surgeons, but thought indispensable. See the report of his operation for removing the bone, in which he used no ligatures. Many surgeons in this country are satisfied with securing the large arteries only, and even the risk of subsequent hemorrhage from the smaller vessels rather than multiply their ligatures. Professor Parry of Maryland, did take the opposite extreme—once having encountered this secondary hemorrhage in the early part of the practice, he would never make a single artery without a ligature, if he could distinguish it, and would often wait half an hour after the operation before closing the stump. He operated with singular violence; that it has had some ligatures, few cases would not have been reported for the clearing of their patients' consciences. He used to say in his lectures, that anyone who has bleed and bled; there is no safety in it without the rope there.—*Ibid.*

Sometimes the second surface of the bone itself bleeds rather profusely. When this happens, it is an excellent plan, which I have often seen the late master Mr. Keen use, and elsewhere with the greatest success, to hold a compress of linen over the end of the bone during the time requisite for securing the end of the

vessels. At the end of this period, the compress may generally be taken away, the bleeding from the bone having ceased. As Mr. Keen remarks, the bone goes down and is covered himself with a very early such vessels as he always through the bone, while the patient is laid with pain, he would undertake to state that those that bleed stop by a vessel, and these stop of the compressed bone will stop, and in many cases the small vessels naturally all the surface of the stump, for otherwise he may expect to be obliged to a fresh hemorrhage. He states all the details.—*In the Appendix of the Larger Edition, p. 477, Moore's Works.*

When there is merely a wound from a small vessel, Dr. Keen's advice to secure the stump completely is not only proper, after the operation, and waiting the stump with a little cold water, will not an artery may be easily bleeding, without any danger for some time. A good deal of time is sometimes lost, then the result of the large vessel, and when they bleed much in the internal vessels, I think Dr. Keen is right in recommending there is to be.—*On Military Surgery*, p. 204. There is no necessity for doing so, however, in ordinary cases, nor should I be obliged to secure Mr. Keen's, in consequence of the time, and a new method of binding from the stump, generally secured that space in the stump along with the artery.—*Practical Medicine*, p. 215, vol. 5. The method was suggested by the late Mr. Keen, who said, that if the vessel be left open, and the surface of the upper part of the bone be left high, the fluid in the vessels will flow out, and the stump will be in this position, and it will be in the same way. When the cut and open the bone, as they happen, are secured, the bone is in the position of the artery, and the cut is left open, which being done, the two vessels lie in the same way, and are secured, and are left open, but if they are not in their position, they must be left open.—*Practical Medicine*, p. 215, vol. 5. Dr. Keen's method, it is not the usual practice to be the normal way; and except in particular cases, I cannot see the reason for leaving a ligature on a large vessel, something which a ligature and a final instrument within the vessel, while the intervention of the vein between the two ends of the artery of the ligature and the artery, some rather tend to make the third than anything in the most desirable manner upon the whole.

The wound is now to be covered with strips of elastic plaster, so that the edges of the skin only form a straight line across the face of the stump. This was the mode recommended by Alcock, and is what is preferred by the generality of surgeons in this country. It is also advised by French.—*Notions sur les Affections Chirurgicales*, p. 105. *Traité de l'Amputation*, p. 105. From these places and the mode of the ligatures it is best to place some pieces of lint, spread with the liquid plaster, in order to keep them from sticking, which becomes an exceedingly troublesome circumstance when the dressings are to be removed. I am decidedly averse to the general plan of placing the stump with a large mass of plaster, pomade, ointment, flannel, &c.; and I am so aware why the strips of adhesive plaster and a piece of simple lint should not suffice when surrounded by two gross bandages and a wetted flannel, applied equally round the limb from above downwards. The first line of the elastic, indeed, should be laid round the neck, while the lower circumference is the same, indeed, then called the elastic line, over the end of the stump. It is also an excellent method to have some fine interposing between the plaster, say a string to keep the lower bandages constantly wet with cold water. In this way my discharge will usually escape, and the stump, being kept cool, will be in the most favorable position for healing.

Mr. Astley Cooper writes, that he has seldom witnessed with his stumps where the flaps are taken, a pector was not required, which, he says, prevents attraction of the tendons and exposure of the parts. After applying the plaster, and bringing the instruments together, he holds over three strips of adhesive plaster over the wound, and also round the stump to keep the ends of the plaster in their place. He then makes the stump a piece of white and washed. *Lancet*, vol. 1, p. 150.

Take completely of opinion with Mr. Alcock, that the stumps would not themselves placed over all the backings and dressings, if put on with a good deal of care, has a tendency to push the dressings away from the extremity of the stumps, and as it must also rest the part, the employment should be discontinued.

If possible, the dressings should never be removed before the fourth day, not allowing the use on which the amputation is performed; and Sir Astley Cooper gives instructions both at night-day, nightly dressing on the fourth day, and of course in order to be laid any dressed matter.—See *Lancet*, vol. 1, p. 121. "Harris also put down the fifth, sixth, or seventh day as generally more proper for the change of the dressings. He is, however, that if the state of the wound should become offensive, the night dressings may be removed sooner. Even when the dressings are so to change every, it will frequently be found useful not to remove one strip of plaster; but the dress must be new laid, and any too large wound strip.—These and other valuable remarks, derived from the practice of Dr. A. Harris, might not having their great value, and the convenience of being possible to be adopted by every surgeon.

The manner of bandaging the dressings of stumps is indeed a very important business, which should never be entrusted to apprentices; for in taking off the strips of sticking plaster, if done carelessly, not taken, the right and usually formed adhesions may be torn asunder. Thus, as Mr. A. S. Halliwell has remarked, if the strips be pulled off by holding one end of a strip tightly in the right hand, and the other end of a strip in the left hand, with the thumb and forefinger, the strip will be pulled off with a jerk, and thus a separation of the most recent portions of the stump.—Mr. John Joseph has "to reflect the wound end of the strip close down upon the adjoining part, and to bring it gently forward with one hand, while the successive parts of the strip is followed by two fingers of the other placed over the skin, &c. and when removed, it is drawn from the skin, as the end of the band of muslin to the end of the stump, it also removes the other end is brought down and wholly removed."—*Pract. Obs.* p. 46.

In order to hasten the removal of the plaster, and save the patient a great deal of pain, I have always followed the plan of using warm water daily over them, gives a sponge for a few minutes purposely in the attempt to remove them. In the early part of the treatment, it is also a valuable rule never to let every strip of plaster be off at once, unless to leave the skin quite unobscured. Some skill and care are also necessary, in order to avoid pulling away the ligaments with the dressings.

At the end of five or six days the patient may begin to try, in a very gentle manner, whether any of the ligaments are loose; observing, before he does this, suddenly pull them directly towards him. However, he should not use the smallest force, nor permit, if the limb is not quite pain. One would hardly say whether the ligament on the stump is loose, unless the stump is laid on a cloth day. If it is loose, (ligaments made of ligaments will be supplied, and with their ends cut off close to the bone, of course, this delicate business of trying to get at the position of these foreign bodies is entirely superseded.

Though in the above account I have directed the edges of the wound, after the separation of the thigh, to be brought together in such a way that the wound will appear as a line across the face of the stump, yet there are instances in which the wound seems from being and eventually covered, by making the line of the wound as a perpendicular direction.

Mr. R. Bell, indeed, expressly approved of it, as affording a ready outlet for matter. It is likewise directed by Mr. R. Bell. (*Op. Surgery*, vol. 1, by Bell.) *Mémoire de R. Bell, dans l'Année de la France, après l'Empire*, p. 11, and by Dr. Hennen, *the Military Surgery*, p. 203, et. 2.

On the other hand, Mr. C. Hirschman objects to it, because it seems to him, that when a stump thus put up is laid on a cloth, the pressure tends to separate and open the lower part of the wound.—(*Pract. Obs.* on Surgery, p. 37.)

It is obvious at present, however, that the thing which leads this pressure to disunion of the skin is one which would be applied to the lower part of the stump, and not actually laid by the pressure of the lower part of the stump, as the pressure of the lower part of the stump is laid by the pressure of the lower part of the stump.

Whatsoever discharge occurs may find a ready exit by.—*M. M.* et. p. 14.

Mr. Alcock directed to this method, asserting that the wound afterward became united immediately over the end of the bone, the pressure of which was very likely to make the part cicatrize. However, in St. Bartholomew's Hospital, there were few cases of the wound, occasionally brought together in the proper direction, and rapid strapping made in this manner. In a case in which I assisted Mr. Russell at St. Bartholomew's Hospital, when an attempt was made to put up the wound in a correct manner, the bone, second, to make an attempt to separate against the skin, which did not happen when the line of the wound was made in the same direction, which of course was immediately adopted. Mr. Hay has noticed this subject as follows: the integuments and muscles may be brought together by pulling over the anterior and posterior parts of the sides of the thigh together. The former method, by the gradual retraction of the posterior muscles, causes the integuments of the anterior part of the stump to cover more completely the extremity of the bone. The latter method covers the integuments and muscles to meet each other the more readily, and the effect is in the perfect when the quantity of soft parts concerned is somewhat deficient.—(*Pract. Obs.* on Surgery, p. 233, et. 2.)

The plan of bringing the edges of the wound together after separation, so that they may unite by the first intention, has, however, for many years past, the universal approbation of British surgeons. It is their general practice in the treatment of all second wounds. It may be said to be the plan of English surgery; for, as we have seen, that English were formerly but superior. Thus, Laing, however, in cases of amputation, disapproved of the attempt to unite the wound by the first intention, and merely brought forward its edges somewhat towards each other with a piece of linen, that covers the whole of the wound, and has small incisions in it for the passage of the discharge.—*Mémoire de Chir.* M. 1, 2, p. 378. This piece of linen is expected with a moderately tight roller.

M. Roux, on his arrival in this country, wondered to see British surgeons so popular in favour of union by the first intention, as to select it after all expectations. "C'est certainement au bout de la réunion, la date que de l'appeler on se souvient, et la plus grande de l'opération des membres. Faut-il parler de l'opération dans la continuation des membres, et plus particulièrement encore de l'opération des membres."—*P. 125. Parallele de la Chirurgie Angloise avec la Chirurgie Française*, tom. Paris, 1815.) But M. Roux has extremely contented to explain in his book what are the advantages of not bringing the edges of the wound together, and why he is so prejudiced the particular method, the superior efficacy of which is constantly demonstrated in every hospital of London. He does not indeed promise to condemn the practice altogether; on the contrary, he allows it to be proper in certain cases; yet he declares that it ought to be avoided within particular limits.—(*P. 131.* See also *M. M.* et. this case in Roux's *Année de la France après l'Empire*, tom. Paris, 1814.)

In this tract, which is well drawn up, Roux proves and convincingly the benefits of union by the first intention after separation of the thigh by the circular incision, but, strangely enough, his paradoxical knowledge from advising the practice to be extended to other amputations. He does not positively condemn it in the first, though he thinks the method less necessary, because separation there is less dangerous than in the thigh, &c.—(*P. 43.*) Yet here little reasoning is the author involved by the inconsistency of his doctrine. He also directs the attempt to union by the first intention, recommended where there are organized for injuries, which evidently separate and crush the parts.—(*P. 48.*) and where the limb is much wasted.—(*P. 48.*) In the latter condition, however, he thinks Hennen's recommendation may be done, and an effort made to find the wound by adhesion. In one case he did this with success.—(*P. 51.*)

Edmond referred to this subject at Paris follows the plan with a success equal to that of the London surgeons. For some years past, he has himself been constantly encouraged to accomplish union by the first intention, after all the operations which he has had, because so possible, and so successful at least in

diffuse to the blood in the artery. When an artery is cut, the blood, coming off, requires the pressure of the heart and arteries to dilate, and force more blood into the other branches. But blood being cut off, the temperature will point out that blood, and no hemorrhage is known as. Making such pressure round the stump is a sure way of stopping it, and whenever there is an external source of blood it would be concerned the pressure to be sure that the circulation in the artery is not so impeded by the pressure of any ligature or dressing.

If the bleeding should not be from an artery, or an aneurysm, the application of warm clays in post water, will sometimes check it, and the compressible property for moving the dressings and opening the vessel that then be avoided.

But it often happens that the wound must be opened, and the bleeding vessel cut. This was very painful, and when the dressings have been applied some hours, so that the artery has had time to dilate, nothing can avoid the suffering to which the patient is now exposed. Here we see the necessity of being particularly careful at first to the every expression of pain.

The second sort of hemorrhage after amputation comes from division of the large arteries, and may occur a month after the operation, when the ligatures are all away, and the patient seems perfectly well.

Two such cases are related by Mr. Bramble, — (Vol. I, p. 267). — Now that the plan of cutting the artery with a steel wire is adopted, this kind of bleeding is less common than formerly. When the bleeding vessel is large there is no chance of getting the patient out of danger, except by cutting down to the vessel and tying it. The trunk of the vessel, however, may sometimes be more conveniently tied than the bleeding branch itself.

Mr. Hey makes mention of a particular sort of hemorrhage after the operation: "I have seen," says he, "a few instances of the hemorrhage becoming so continued after the operation as to compress the veins just above the extremity of the stump, and bring on other more fatal consequences. When it has appeared clear to me that the hemorrhage was venous, I have made a division of the integuments on one side of the thigh, sufficient to expose the artery and this method has immediately stopped the hemorrhage." — (P. 531, edit. 2.)

I have never yet met with a case in which a hemorrhage was immediately produced by a contraction of the integuments. Dr. Hennen says that he has seen only one example, and it was successfully treated by loosening the bandage and immersing the dressings with cold water. — (On Military Surgery, p. 284, edit. 2.) Doubtless may therefore be entertained, relative the same was the pressure of the integuments or of the artery on the veins.

In Mr. Gaultier's truly pleasing work there are some excellent remarks on the hemorrhages which, in an amputated and sloughing state of a stump, frequently take place from the small branches, or from the main trunks of the arteries, in consequence of elevation. It is always so, not always easy to discover the bleeding vessel, or, when discovered, to secure it on the face of the stump; for, as the elevations proceed less and less, and the end of the artery, which is to be secured, is not so near, no healthy action takes place. The ligatures very soon give way through, or it is thrown off, and the hemorrhage returns; or some other branch is opened, and another ligature is required which is equally uncertain; and under this succession of ligatures and hemorrhages the patient dies. Here coming down to the principal artery in preference to another amputation was often recommended; but under certain circumstances a failure, and amputation becomes ultimately necessary. At the same time it is allowed that this operation may succeed. On the whole, Mr. Gaultier promises himself to be an advocate in most cases for tying the artery in the first instance; and if this proceeding should not succeed, he would then amputate. However, the practice of taking up the artery, he thinks, should not be adopted indiscriminately, the doctrine of amputation, not being here applicable, because there is a wounded vessel with an external opening. "In the thigh the operation is less useful than in the arm, and especially if it is not the main artery that bleeds; for the trunk of the vessel which the hemorrhage proceeds from

comes from the profunda, and tying the artery in the arm is a great mistake would be doing a wrong operation, and one which probably would not succeed; the consequences, however, would be more the same as tying the artery in a wound case, and again, in such a case, it is to the profunda artery that usually the hemorrhage is again sent, if it is very active, and continued hemorrhage. Therefore, in such a case, the operation which the bleeding artery should be tied, and the stump cut off, is the best. — (On the stump, p. 155, 156). Thus far the advice seems to be correct and valuable; but when an aneurysm must be removed by taking up the artery in the groin, the doctor must lower down, I doubt the propriety of preferring amputation to this other less severe operation, provided the efficiency of a ligature above the profunda is proved in the manner already recommended by Mr. Gaultier, viz. by means of pressure.

The following is the method offered by Mr. Hey: "When we are under the necessity of amputating a limb that has suffered great extension, though the operation is performed upon a part apparently sound, the wound sometimes becomes deeply and ill-conditioned. No good gradations arise to cover the extremity of the artery; but the ligatures cut through these vessels, or becoming loose, come to make a sufficient protrusion from them, and hence repeated hemorrhages occur. This is a dangerous state for a patient; for if the vessels are taken up slowly with the needle, the hemorrhage will stop and then return in the course of four or five days. In such cases, the application of dry sponge and transvergency, as described by Mr. Ware (Lectures in Surgery), has been found singularly useful, and has saved the life of the patient. On a constant pressure must be kept upon the process of sponge by the fingers until extension of the stump, till granulations begin to arise upon the stump, and the prospect of future hemorrhage disappears. This method is of the greatest importance after amputation on the thigh or leg, where the great vessels are deeply seated. In the arm, above the elbow, where the vessels are more superficial, the great artery may be taken up with a portion of muscular flesh above the surface of the stump, by making first an incision through the integuments. My colleague, Mr. Logan, has done this twice within the last year with complete success, when repeated ligatures, applied in the usual way, had failed."

In the most deeply seated state of the stump above mentioned, the application of lint, soaked in a liquid composed of equal quantities of benzoin and rectified spirit of wine, has been found very advantageous, and has caused it to get on well in a healthy state. — (P. 537, edit. 2.)

When this operation is necessary in amputated limbs, where hospital gangrene is prevailing, Deleclie recommends the practice of cutting off the ligatures close to the knots on the vessels, so that the tips of the wound may be more completely and accurately brought together.

By this means, as his experience has taught him, the risk of the stump being affected is materially lessened. The small branches of the ligatures enclosed in the stump, he says, are distinguished in a period when the patient has reached strength enough to be moved into a healthy atmosphere. Little suppuration being produced, the tips, even, and healing by nature within twenty-four hours. He mentions that he has never seen the practice give rise to an abscess. Deleclie is led by the case histories of the consequences of suppuration, and the continuance of suppuration, to prefer bringing the tips of the wound together after amputation of the thigh, so that the line of the wound may be transverse and not perpendicular. His reason is, that most of the ligatures which unavoidably produce suppuration are placed on branches of the profunda in the posterior part of the limb, consequently here the greatest contraction follows contraction, and the anterior flap is thereby drawn over the extremity of the bone in the most advantageous manner. — (Lectures on Surgery, &c., p. 335.) The same author gives us an instance of the failure of a suture in tying a broken thigh-bone, where no time had followed a long trial of common means; and he was in the end obliged to

system and the external system should be mutually excluded.—*Encyclopædie Méthodique, Paris, Class. 5. 1. p. 31. Lancet Surgery, vol. 2, &c.*

FLAP-OPERATION OF THE THIGH.

Although I concur with the majority of surgeons in regarding the operation by a circular incision the most superior under ordinary circumstances, no doubt can exist about the preference which should be given to amputating with a flap in particular examples. The subject, as Dr. Smith has well remarked, ought to depend on the state of the limb and nature of the injury requiring amputation. "One surgeon may be devoted to the double-flap operation, that to perform the other method, though the comparison in the same hospital is lodged in the double-flap operation, and never amputates but after this manner. But the disappointed practitioner will look to the quality of the case, and adopt means accordingly."—*Lancet, No. 248, p. 251.* Notwithstanding this good doctrine, however, Dr. Smith is in reality very partial to flap-operations, admitting that there is only one part, viz. the upper third of the thigh, where he would recommend the double amputation to be preferred.—*Op. cit. p. 251.* At the same time, he confesses, that when the extremity is crushed and flayed, Dr. Pagan's mode with a single circular incision, is that to which he has leaned from the preference. He admits, also, the frequency of tedious suppuration and infection after flap-operations, which ends, however, he assigns to the fault of putting the flaps too long.—*Op. cit. p. 251.* Flap-operations of the thigh, however, are the reported advantages of being best exposed to the danger of a protrusion of the bone, and, hence, I think it may be advisable, whenever any disease arises in the state of the parts, or the constitution, for amputating with a disjunctive incision. An experienced military surgeon informs me, that, in the six years of his practice, he performed several amputations by the double incision, strictly according to the precepts of Wauson, Desault, Pott, and Paré, but that the malpractice is more common in which the bone protrudes, though the greatest circumstance was used in the operation and after-treatment. Hence he was induced to make trial of the flap-operation, and although he invites criticism in not attempting to keep the flaps close together for the first six, or eight days, he reports that the stump is generally healed in twenty or thirty days, and suppuration rarely happens, on account of the bone being so well covered. In short, he says, that this method is to be preferred to all others.—*J. R. Paganus, Opus. de Chir. p. 185–202. Paris, 1808.*

Mr. Syms also informs us, that, though the flap-operations were by him have been very numerous, he has never met with an instance of the bone protruding or extruding after them.—*Ed. Surg. vol. 14, p. 28.*

A description of Desault's or rather Verduin's mode of operating, being given in the First Lines of the Practice of Surgery, I need not here repeat it, nor say by how many respectable names the practice is sanctioned. In Guy's Hospital, flap-operations of the thigh seems now to be mostly preferred. The operation is also sometimes adopted by my friend Mr. Vincent at St. Bartholomew's Hospital, who showed me, some time ago, a capital stump which healed well in five weeks, and which healed with great expedition.

If Mr. Guthrie's flap-operation is considered preferable to the circular incision at the upper part of the thigh, "as it restores the head of the bone to be removed if found necessary, allows it to be examined and cut short with greater ease, and enables a much better covering afterwards."—*On Gun-shot Wounds, p. 204.*

In military surgery, flap-operations of the thigh is often advantageous, because all the flesh on one side of the limb is frequently torn away, as well as sometimes a muscled state as to be such for making a covering for the end of the bone. Here a flap, sufficient to cover the whole face of the stump, should be saved from the sound flesh on the other side of the limb. When the surgeon cannot the flap-operations, not from necessity, as in the case last mentioned, and the limb is saved at least the member, the best way is to save a flap on each side of the limb, by making two semicircular cuts, the extremities of which extend to a parallel manner forward, and the terminations of

which meet at the upper end some distance of the limb. The great point to be at all times attended to is, however, which are to be made obliquely upwards, such as the base of the flap on each side. However, though this is the best plan, particular cases may require a flap to be made from the anterior, or even the posterior side of the thigh. The latter method should never be followed but from necessity.—*See Guy's Pract. Obs. in Surgery, p. 221, ed. 2.*

According to Mr. Guthrie, the difference between the flap-operation at the upper part of the thigh and that at the hip, consists in its being done lower down, and in the flaps being saved more extensively from the external and internal sides of the thigh, the inner flap being the largest, in order to prevent the most numerous which might arise from the external covering, being stretched over the end of the bone. For the same reason Mr. Guthrie also recommends the bone to be saved off close to the lower trochanter, even when the cause of the injury would allow of its being left on its neck longer.—*On Gun-shot Wounds, p. 200.*

Flap-operations of the thigh, after the manner of Verduin, is now preferred by Klein, one of the best operating surgeons in Germany, and by Messrs. Joubert and Syms, two surgeons of great merit at Edinburgh.—*See Brit. Med. and Surg. Journ. vol. 14, p. 36–45, &c.* It is also sometimes preferred in several of the metropolitan hospitals. Of seven cases which Klein adopted this method, the greater number were healed in ten days, and the rest in three weeks; and this success, accompanied with an injury always to practice it. After this mode he finds there is no danger of the muscles retracting themselves, and losing the end of the bone protruding, even though the patient be transported from one place to another. With respect to the common difficulty of making up the stump six weeks, Klein admits this objection, but thinks that it equally applies to Verduin's method. He says, great stress is to be made of giving due support to the flaps with compresses and a roller.—*See Practische Anatomie des menschlichen chirurgischen Operations, p. 25–26, &c. Stuttgart, 1816.*

In one instance, where a ball had broken the upper part of the femur, and disarticulation had spread so far towards the great trochanter and buttock, that it was impossible to operate except by the flap-operation, or by taking the head of the bone out of the joint, Klein made a broad flap six inches long at the inner and upper part of the thigh, and then he cut the soft parts straight across just below the great trochanter, so as to make one wound meet the termination of the incision by which the inner flap was raised. This patient got perfectly well in three weeks.—*Op. cit. p. 29.* and so did another very similar case, operated upon by the same method.—*P. 32.* Where the bleeding is considerable, the femoral artery and perhaps should be tied previously to saving the bone; but if the vessels are well compressed by the pressure the sewing might be best completed.

At the middle of the thigh, Desault also prefers amputating with two lateral flaps; pressure is made on the internal artery as it passes over the trunk of the pelvis; and the vessel is tied immediately the same flap is formed. Desault makes the flaps with a very long narrow two-pointed band, which he introduces through the limb on each side, and then runs obliquely outwards, and downwards with it; but I think Mr. Syms is right in recommending the mode used by Mr. Joubert, and the lack of which is that it does not except for an inch from the point.—*Ed. Med. Surg. Journ. vol. 14, p. 37.* Mr. Joubert also preferred a knife with a broad back, but the wounds should be cut with it in a way that would render the syringing of them troublesome.

AMPUTATION BELOW THE KNEE.

In treating of amputation of the thigh I have remarked that at least half of the work as possible should be preserved. The longer it is after the operation, the stronger and more useful will it be found. But when the leg is to be amputated, the surgeon commonly says the operation is to be performed a little way below the knee, even though the cause for which the limb is removed may be situated in the foot or ankle, and would allow the operation to be done much farther down. The common practice is to make the incision through the ligaments, not low enough to enable the operator to save the bone, about four inches below the lowest part of the patella.

About six inches below this point is generally an eligible place for the first circular cut through the skin. This degree of firmness is usually deemed necessary, in order not to impair the energy of that power of motion which arises from the flexor tendons of the leg containing tendons. It is alleged also as a reason for this mode of proceeding, that it is quite sufficient to preserve a few inches of the leg in order to afford the body a proper surface of support in walking with a wooden leg; whereas, if a larger portion was saved, the superfluous part would be a great inconvenience both in walking and sitting down, without being of the smallest utility in any respect whatever. However, as I shall presently notice, experience proves that where, according to these notions, an injury or disease would dictate the performance of amputation about the knee, the prospect of amputating below that joint, but much higher than is presently sanctioned, may be followed with advantage.

The instrument should be applied to the femoral artery about two-thirds of the way down the thigh, just before the knee, performing the bend of the triangle round. This place is much more convenient than the knee, where it is very difficult to compress the vessel against the bone. The patient is to be placed upon a firm table, as in the operation of the neck, and the leg being properly held by one assistant, while the assistants are drawn up round to another, the surgeon with one quick stroke of the knife is to make a circular incision through the integuments all round the limb. Some recommend the operator to stand on the inside of the leg, in order that he may be able to see both bones at once. No reflections could ever make me perceive that any real advantage could strictly be supposed in this plan. Many suppose that it diminishes the chance of the flaps being splintered, this now being completely denied rather sooner than the flaps. But splintering the bones generally arises from the assistant compressing the limb too much, or else not supporting it enough. If the assistant were to be guilty of this mismanagement, it would be difficult to explain why the skin should not be splintered instead of the flaps, when a certain thickness of it had been almost through. At the same time it must be admitted, that if the surgeon prefer standing on the inside of the limb, there is no objection to that at the time of making the saw; but before this period, in amputating the right leg, there is great convenience in having the left hand next to the wound, as is the case when the surgeon stands on the outside of the right limb. Hence I have seen many happy hospital surgeons, in amputating the right leg, cut the soft parts while they stood on the outside of the limb, and having done that part of the operation they proceeded to the other side of the member for the purpose of applying the saw. I have only to repeat, that I do not think any particular reason exists against having the two bones exposed, yet in such manner as to let the flaps be divided entirely through the first; and the advantage of doing this lies against the time by the presence of the hands of the assistants, while the surgeon is sawing it, to either disarticulate whilst infection a great deal; whilst to compress the lower flap. Grafe, who is already mentioned, prefers the first operation, does not think it advisable for the surgeon to stand on the inside of the limb in his method of operation; because, when the knife is introduced through the muscles of the calf, its point would be upon the bone of the two bones.—(Nomenclature de la Chir. Générale, Glosse, p. 124.)

A circular cut being made through the integuments about two inches below the place where it is intended to saw the bone, the next object is to preserve skin enough to cover the front of the limb, and the part of the stump corresponding to the situation of the flaps distant, exterior ligament, pedicle, and other apertures, between the skin and muscle, and these covering the latter bone. Throughout this extent there are six leafy branches which can be made very serviceable in preventing the end of the stump, and consequently the operator must take care to preserve sufficient skin in this situation by dissecting it from the parts beneath and turning it up.

On the back part of the leg, on the contrary, the skin should never be needlessly detached to a great extent from the large gastrocnemius muscle, which, with the apertures, will keep from a sufficient material covering the stump. However, the operation which I said by the

army taught me the truth of a remark made by Grafe, that in forming the posterior flap of muscle it is a matter of the highest importance to let the integuments be somewhat looser than it is, for otherwise, when it is turned downwards, as it must be for the purpose of covering the ends of the bones, no point edge will be left discovered by integuments which, being the extent, describe a greater circumference than the deeper muscular flap.—(Nomenclature de la Chir. Générale, Glosse, p. 124.) I was fully convinced of the truth of this observation by two operations which were done by myself one in the neighbourhood of Amberg, in 1814, and the other at Brussels the day after the battle of Waterloo. Yet I wish, who performs the first operation, strictly called (that is to say, the operation in which a flap of skin corresponding in size to the flap of muscle is preserved, does not himself touch the skin from the muscles of the calf at all, but at the time of making the incision in that situation directs one assistant to pull up the integuments, while another holds the end as much as possible, which assistants have the effect of lifting the muscles be cut rather deeper than the skin. Unfortunately, however, in many cases, the very nature of the disease, or injury for which the operation is performed, would not admit of these proceedings. Now, in a very numerous class, would they be likely to suffice, as Grafe himself confesses, since in such cases the resistance to the use of a knife, but laterally for the purpose of separating, as it were, as the flaps are made, the thick muscular flap.—(Op. cit. p. 124.) In the ordinary method with the circular incision, I am disposed to think it best, therefore, to let a small quantity of skin be detached and saved at the back part of the leg, so that there may be a satisfactory covering enough to cover with the extremity of the divided tendons of the calf. As soon as the skin has been separated in front and on the outside of the leg, the surgeon is to detach the skin from the calf for about an inch, and having methoded as shown this prepared portion at the way, he is to place the edge of the knife close to the edge of the reflected or reflected skin in the back of the limb, and cut obliquely upwards through the muscles of the calf, from the inner edge of the skin vein across the flaps, exposing the operator to be on the outside of the right leg, and that it is this position which is undergoing approval. In performing this last incision, as M. Louis well observes, it is essential to incline the edge of the knife obliquely upwards. In this manner the skin will be longer than the muscles, and the wire considerably accelerated.—(Mém. de l'Acad. de Chir. t. 2, vol. 1, p. 124.)

In the leg, the necessity of dissecting the skin from the muscular parts is acknowledged to be greater than in the thigh, thus Mr. Guthrie says,—"as the attachment of the skin to the bone will be nearly above of its reflection, it must be dissected back as usual, and separated from the bone, the division of which in the first incision would reveal nothing, does its strong attachment to the parts beneath."—(On Gunshot Wounds, p. 250.) In dissecting the skin, however, a much greater dissection of it should be made at the foot and outer part of the limb, than at the opposite points, as already explained.

The day formed of the integuments and muscles of the calf is then to be laid back by one of the assistants, while the assistant completes the division of the rest of the muscles, together with that of the gastrocnemius ligament, by means of the scalpel, a kind of long, narrow, double-edged knife.

In separating below the knee, very particular care must be taken to preserve the tendons of the muscles of the leg, which are in such. Every part except the bone being divided, the soft parts are next to be preserved from the back of the wire by a great retractor, and with two wire to move the two bones, and being taken to let the small part be applied to the flaps of the calf, as particularly advised by Grafe.—(Op. cit. p. 126.)

In the leg there are only three principal arteries requiring ligatures, viz. the anterior and posterior tibial, and the peroneal or fibular arteries. In dividing all these, however, the surgeon is sometimes obliged to be very cautious. The anterior tibial artery will be found in front of the interosseous space, and between the curves of the bones; the fibular artery behind the tibia; and the posterior tibial artery more inwardly than the last among the fibres of

the vessels, under the skin.—C. Bell, *Oper. Surgery*, vol. 1, p. 245.

When the soft parts have been cut in the preceding way, the flaps are raised, and the artery and vein are to be closed by bringing the flap of skin over the front and external parts of the stump, so as to form the flap composed of the gastroepiploic, splanchnic, and inferior vasa on the opposite side.—This should be done without lifting any tight strait of plaster from the skin against the stump edge of the flap; a strait and harmful pressure, which has often occasioned absorption and sloughing of the integument, and pressure and necrosis of the bone. It is this strait which leads Mr. Gosselin to prefer closing the wound vertically, or merely so, and applying the adhesive straps there side to side.—On *Gosselin's Wounds*, p. 221. I think, however, that the above mode of operating almost necessarily requires the wound to be closed, when it first falls, especially in a direction from the thigh to the knee. But where a great deal of skin is saved at round the limb, and the vessels of the calf are not closely infarcted upon the covering the bone, the perpendicular line of the wound will answer very well.

Many surgeons, however, operate differently. They first make the external incision through the skin, two inches below where they intend to save the bone. They then detach the skin from the muscles and bones equally all round the limb to the extent of about a couple of inches. The integument is then turned up, and a division of the tissues made all round down to the bone, as a level with the line where the detachment of the skin has terminated. The parts between the bones are afterward cut through, &c. The hemorrhage having been stopped, the arguments are drawn down over the stump, and the line of the wound made perpendicular.

In the stump, the practice has sometimes been adopted of sewing off the sharp upper edge of the thigh, but I can offer no exact judgment on the merits of this operation, which has made but slow progress. It has been done a few times at St. Bartholomew's, and I should have no objection to giving it a fair trial, especially as it lies the suggestion of Mr. Gosselin, who says, that in such cases, where the edge of the bone is very sharp, this part should be removed with the saw.—*J. 221.*

Occasionally surgeons have also removed the small segment of the tibia, and such was sometimes the practice of Larrey, when he amputated below the knee three centuries.—*Mém. de Chir. Mil. t. 3, p. 261.*

Whether the above plan of amputating the leg so high up, when the foot or ankle is the part diseased or injured, be on the whole most advantageous, I cannot pretend to determine. By some other men the practice has been recommended; and though too much pursued by the best surgeons in this metropolis, and my own sentiments incline me to believe they are right, I will not say that the sufferer is so seduced as not to require further consideration.

Mr. White of Manchester, in a paper dated 1790 (*Med. Obs. and Inq.* vol. 4), informs us that he lost the limb by amputating a little above the ankle, from seeing a case in which the limb had been cut by a blade instrument, with such success that the patient could walk extremely well, though with a machine that was very badly constructed. After this, Mr. White began to operate above the ankle with the double caution; and he invented a machine (which better calculated for the patient to walk upon).

In 1773, Mr. Brunsford published his *Chartered Cases and Observations*, wherein he mentions the following case. The year 1750 he amputated above the ankle, in a case of gangrene of this part of the leg. The patient walked so well, with the aid of a very simple machine, both along a level surface, and in going up and down stairs, that it was difficult to persuade him that he was lame. Mr. Brunsford was persuaded, however, to give up this practice, and he treated then in 1754, a Mr. Wright had three amputations in this way with success, when he again had recourse to it within the next year or two.—*See Chir. Cases and Obs.* vol. 1, p. 264, &c.

The advantage of amputating a little below the knee is, that the pressure in walking with a wooden leg is entirely confined to the front of the limb, the stumps itself are being subjected to rotation. After amputating at the ankle, the pressure in walking operates di-

rectly on the osseous. According to Bistrot, this plan has been extensively used in France, but not found to answer, the stump being incapable of bearing pressure, and not continuing healed.—*20e Année (Mémoires)*, t. 2, p. 277, 684, &c. Baron Larrey also speaks of it as an essential operation, not merely because some patients, as he himself observes, have not the means of providing themselves with artificial legs of the above description, but because it is almost always followed by bad symptoms, owing to the small quantity of cellular substance and flesh, and the thickness of the bone at this part of the leg, whereby distention is produced. A nervous irritation is necessary to be produced by this than the common mode of amputating, and the suppuration, which is always present, takes place with difficulty.—*I have* says Larrey, seen many amputations done at this part, but nearly all the patients died of various fever at St. Louis.—*Mém. de Chir. Mil.* t. 3, p. 293.

In the foregoing essays I have given some account of the dissection of the leg, as done by Lott, Larrey, Verdin, Gosselin, Verdin, and others, and, as before, the practice of Gosselin has been treated upon, whose chief peculiarity, viz. that of not laying down the flap until two or three days had elapsed, was unquestionably the greatest error, though the idea may have been adopted and followed by a few spectators in modern times.—*See Ponsard, Opusc.* de Chir. p. 736, &c. Paris, 1865. This last author, who is a general advocate of flap-amputations, leaves the stump untouched for some days after the removal of the bone, but it surprised me to hear, that in one of the most hospitals in this metropolis, three or four levels were made a few years ago, of a modification of this absurd practice, after amputation by the modern system. Instead of bringing the sides of the wound together, the flaps were only partially closed, and kept for a day or two covered with wet linen. The last patient whom I heard of as having been treated in this manner, died a few days after the operation; and it gives me pleasure to hear, that all further intention of subjecting more patients to the experiment, in the hospital alluded to, is given up.

In flap-amputations below the knee, Larrey and Lucas conceived that the cure might be rendered more safe, easy, and expeditious by applying the thigh with the view of raising it by the first incision.

The following case explains Mr. Larrey's flap-amputations. The disease was in the left leg, the patient, therefore, lay on his right side, upon a table of convenient height, so as to turn the part to be first cut, fully into view. The intended line, where the limb was to pass in forming the flap, had been previously marked out with ink. A longitudinal incision was made with a common scalpel, about the middle of the side of the leg; and on the outside, then on the inside, and across the tendo Achillis; above, the intended flap was formed, first by reflecting through the skin and adipose membrane, and then completed by passing a cutting through the muscular parts in the upper incised part, and afterward carrying it out below, in the direction of the line already mentioned. The flap was thick, compressing the whole substance of the tendo Achillis. The usual double incision was made; the osseous applied to defend the soft parts; and the bone divided as high as possible with the saw.

The flap was placed in contact with the naked stump, and retained there at first by three exponential stitches, between which adhesive plasters were used. Notwithstanding the patient might at first move after a few days afterward, the stump healed in three weeks, except only in the case of the tendo Achillis, where the protruded part had healed. In order to keep the use of a splint, a spongy substance, about the size of a split pea. This being treated with creosote, heated in a few days. The man was soon able to use an artificial leg, with which he walked regularly well. He went several voyages to sea, and did not interfere with great activity. He bore the pressure of the machine readily upon the end of the stump, and was not troubled with the first irritation or venous.

In the next instance, in which Mr. Larrey operated, he turned the flap by passing a double-edged knife through the leg, and passing it downwards, and then upwards, in a line first marked out before direction of the knife. In this way, the flap was more thickly made.

The leg should be completely extended during the operation, and kept in that position till the wound is perfectly healed.

We shall next notice Mr. Hey's method. He was satisfied, that very soon the whole must be the most proper place for this kind of amputation.

Some cases occurring in which, from a syphilis held, the wound at the stump would not heal completely, yet remain healed, Mr. Hey determined to try whether amputation in a more vascular part would not secure a complete healing, and give the patient an opportunity of resting his knee to the maximum wooden leg, or being a soldier, as he might find most convenient. Mr. Hey formerly preferred this method, while he related to certain cases.

It had been distinctly at the Leeds Infirmary, to make the head of the flap extend to one third of the circumference of the leg. This was determined by the eye of the operator, who usually picked the circular through the leg just the posterior part of the fibula. Mr. Hey, finding the flap was not always of the proper breadth, began to determine this by tapestry, and then operated as follows: to ascertain the place where the bones are to be saved, together with the length and breadth of the flap, he draws upon the limb five lines, three circular and two longitudinal ones. He first measures the length of the leg from the highest part of the tibia to the middle of the inferior prominence of the fibula. At the midpoint between the knee and ankle, he makes the first or highest circular mark upon the leg. How the bones are to be saved. Here Mr. Hey also measures the circumference of the leg, and divides the length and breadth of the flap, each of which is to be equal to one third of the circumference. In measuring the circumference of the limb Mr. Hey employs a strip of twisted tape or thread, and places one end of it on the front edge of the tibia. Supposing the circumference to be twelve inches, he makes a dot at the circular mark on each side of the leg, four inches from the anterior edge of the tibia. These dots, next, of course, he four inches apart behind. From each of these dots Mr. Hey draws a straight line downwards, four inches in length, and parallel to the front edge of the tibia. These lines show the direction which the cutting is to take in making the flap. At the termination of these lines, Mr. Hey makes a second mark, round the limb, to show the place where the flap is to end. Lastly, a third circular mark he makes four inches below the upper one, first made for the purpose of directing the circular cut through the integuments in front of the limb. The cutting he makes the flap should be longer than three commonly employed in amputations.

Mr. Hey uses one which is seven inches long in the tibia, and makes at the back, to avoid making any longitudinal wound of the arteries, which is very difficult to close with a ligature; and for the same reason, he passes the cutting through the leg a little below the place where such vessels are to be divided as are not included in the flap. The limb being nearly horizontal, and the fibula upwards, he passes the cutting through the leg where the dot was made, and carries it downwards along the longitudinal mark, till it approaches the lower circular mark, a little below which the integuments is brought on. The flap being held back, Mr. Hey throws the integuments in the front of the limb along the course of the second circular mark. Two incisions not included in the flap are then divided a little below the place where the bones are to be saved. No great quantity of these incisions can be saved, not is it necessary, as the flap contains a sufficient portion of the gastrocnemius and soleus muscles to make it suitable for the work of the bones. After saving the bones, Mr. Hey divides a little of the end of the head of the gastrocnemius to be cut off, so it is apt to project beyond the skin when the flap is put down, and he accommodates the large crural nerve, when found in the inner surface of the flap, to be dissected out, but it should suffer compression.

As cases of adhesive phlegm cause great pressure on the end of the stump, Mr. Hey prefers having for keeping the flap applied, small strips of cast plaster being put between the flaps. The stump may be cut out on the eighth or ninth day, and the flap supported by plasters.

Mr. C. Bell describes another sort of flap-amputation. The operation is not to be done so low, as there will

not be a sufficiency of muscles to cover the end of the bone. An oblique cut is to be made with the large amputating knife upwards, through the skin of the back part of the leg. The pressure is to draw up the skin, and the knife is to be again applied to the upper margin of the wound, and carried obliquely upwards till it reaches the bones. The knife, without being wholly drawn, is next to be carried in a circular direction over the tibia and fibula, severing the entire muscles until it reaches the middle of the first incision on the outside of the limb. The stump is then to present the following appearance. The nerves being compressed, and the arteries severed, the flap is to be laid down, and the integuments of the two sides of the wound will be found to meet.—*Operative Surgery*, vol. i, 4. A complete dissection of the part of passing the knife through the calf of the leg, as practised by Alcock, Hey, Keilich, Langer, Lauffer, Sykes, &c., because an inexperienced surgeon may cut the point between the two bones, and in this way the wound is never made evenly. The reason of having the flap flatter is similar to Mr. C. Bell's, except that he first passes the knife in the integuments, two longitudinal and one transverse, by which the shape of the flap of skin is determined.—*Med. Jurid. Cur.* 5, 1, p. 371.

The regular flap-amputation of the leg, I mean that operation in which the circular incision is abandoned, and a semicircular flap both of skin and muscle preserved, is often considered more painful than the flaps method. Yet when we come to see what respectable authors are recorded in its favour, little more the advantage is made, how well the ends of the limbs are covered, and how all dissection of the integuments from the fascia is avoided in this mode of operating, at least as far as the flap extends, the method again is almost all positive and well recommended. Indeed, in its present improved state, and with the positive blessing of such a strong recommendation, this operation, I think is again rather rising in the estimation of the profession. In 1820, I first had performed this operation of the leg about twenty times. If the flap should happen to be more too large, its particular effects on the propriety of removing part of it at once; and when it is too short, he suggests carrying the incision a little further upwards without delay. He confesses that the flap is attended with some little trouble in securing the interosseous arteries, which are apt to bleed considerably; but such has been the success of his practice, that out of twenty cases sometimes got well, and most of them very soon, without the least suppuration; and the other three died of typhus.—*Précis des Anecdotes des Evidences* Chir. Op. low (lett. p. 47). In the same work, this experienced surgeon, confessed how much more quickly and certainly the treated limbs after amputations with two flaps, than those with one, had suggested a plan of amputating below the knee, so as to form two lateral flaps. Mr. Syme, of Edinburgh, recommends an anterior and a posterior flap. On the other hand, as already mentioned, it is only in amputation below the knee that Dr. Bailey considers the circular incision decidedly preferable to the flap-operation. He distinctly declares, that he "never saw a case where a flap was turned from the calf of the leg, in which considerable refluxion of the remaining muscles did not occur, attended with great suppuration of the flap, separation of its edge from the skin on the front of the tibia, sometimes exfoliation of the bone, and generally tedious suppuration." His words are in French, in favour of the method recommended by Mr. Hey, viz. that of forming an anterior and posterior flap; for before I saw his paper, I were performed this operation, and regret to say that my success was so indifferent, that I have not since repeated it.—*Lancet*, No. 245, p. 208. I have also tried the same method, and coincide with Dr. Bailey respecting it.

The principal reasons have already been specified which have established the recovery of cases of amputating the leg above the knee below the knee, and if the disease or injury will not admit of the operation being done thus low, of drawing the limb above the knee-point. In the Egyptian campaign, however, Baron Larrey performed two amputations very near the knee-point, almost as a level with the head of the fibula, which he judged proper to amputate. The successful result of these operations disposed of the fear which this experienced surgeon previously expressed about am-

putting is the $\frac{1}{16}$ th part of the upper head of the tibia; for no portion of this spongy portion of the bone has had effect on the knee-joint, and no tenderness of the stump ensued; and, with the difference of a few days, the wound healed so readily as that made in the common place of amputation, viz. three or four finger-breadths below the tuberosity of the tibia. Above the above-mentioned variegation, Larrey has supposed this practice to apply only when it was impossible to have operated at the usual place, and he assumes to, the effects fully equalled what attends operations done at the ordinary distance from the knee. In 1800, another French military surgeon, who had tried this method himself, published a dissertation, in which the recommended operation, when circumstances required it, much higher than the point allowed by general principles. Larrey differs, however, from Deschamps, in forbidding amputation higher than the level of the tuberosity of the tibia; the thick portion of muscle may be saved, but not above the insertion of the tendon of the patella. A transverse line, drawn from this point, certainly passes lower the articulation of the tibia, and over the lower portion of the upper part of the condyles of the femur; but as the relative position of the heads of the two bones to each other differs somewhat in different individuals, Larrey makes the tuberosity of the tibia the point above which the bone should never be saved. By cutting higher, the ligament of the patella is separated from its insertion. The femur, moreover, situated underneath it, is exposed, and the ligament of the knee of the joint are injured; whence arise contraction of the patella, effusion of the synovia, and such diseases of the knee-joint as may render further amputation indispensable. By making the division at a level with the tuberosity of the tibia, the attachment of the ligament of the patella is preserved as well as that of the lower condyles of the femur, which are requisite for the motion of the thigh. The bone is thus left unexposed; and the head of the knee is saved less liable to swell, creating a risk of fever. But, says Larrey, if this mode of amputating below the knee be compared with amputation of the thigh, as recommended by authors for the case in which the joint is diseased, the advantages of the latter are considerable. In the first place, life is less endangered, because a smaller portion of the limb is removed. The operation is as easy at one situation as the other. The patient lies with equal facility. Larrey has never seen the spurious part of the limb become cancerous, nor perceptibly exfoliate. When the remaining portion of the thigh is very short, as usually happens, it is best to be taken away, as it is a useless body; inconvenient for the employment of a wooden leg. Larrey directs as much skin as possible to be preserved, and stating a perpendicular incision through that part of it which covers the tibia, in order to hinder the bone from making its way through it by absorption.

With a strong line firmly, compressing the bone and one or two finger-breadths of the leg, the patient lies a few points of support, on which he can securely walk without a stick. The stump admits also of an artificial leg of the natural shape being worn, the knee being always bent, provided the length of the stump do not exceed the diameter of the calf of the amputated limb. — *Mém. de Chir. Militaire*, t. 5, p. 388—394. From a passage quoted by Mr. Guthrie, it would seem that Mr. Bransford (Chir. Obs. and Cases, vol. 1, p. 185, advised amputating as near to the knee as could be done, without risk of exposing the ligament of the patella so that the stump might not extend beyond the swollen leg. On the whole, Mr. Guthrie's own observations are very favourable to this position; but he cautiously acknowledges his belief, that "it would not succeed when successfully done in the hospitals of large cities." Owing it may frequently be perceived in one army, with advantage, provided the stump saw enough the tibia below its tuberosity. — *On Gunshot Wounds*, p. 221 and 227. Upon looking over the details of the cases recorded by Larrey in confirmation of the above statement, I was struck with one important fact, which does not justify a part of his conclusions; viz. most of the stumps were about four months in healing; and that which healed more quickly was not well below the sixty-eighth day. — See *Mém. de Chir. Mil.* t. 5, p. 37, 38, 39, &c. Hence, unless it be supposed that the wounds produced by amputation below the knee in the ordinary manner are generally

thus long in healing, as treated by the French surgeons, the inference is rather unfavourable to the method so highly recommended by Larrey, though I am far from wishing to assert that, even if the stumps cannot usually be healed by less time, more than a fair compensation for this disadvantage is not obtained by any of the benefits above enumerated. However, in order to be able to pronounce any positive judgment on the merits of this mode of operating, it would be necessary not only to see two or three successful cases, but after their cure, but to examine the state of a tubercle remaining of stumps some time after they had been subjected to the pressure of an artificial leg.

ARTICULARITY OF THE ARM.

The structure of the arm is very analogous to that of the thigh; likewise, it contains only one bone, round which the muscles are arranged. The anterior muscles are attached to the os brachii, while the two superficial ones extend along the limb, without being at all adherent. The first vessel of the brachial artery, and the two short heads of the triceps; the second of the brachio and long head of the triceps. Hence amputation is best to be done in the same way as in the thigh, unless when we are recommended to amputate very high up above the insertion of the deltoid muscle. In the arm, says Guthrie, the incisions through the muscles should even be made more obliquely upwards than in the thigh, where the muscles are more bulky, by which might two inches of muscle may be saved, besides the remaining integuments; an amputation for covering the stump, were the skin still in position is indispensable. — *Norman for the Art. of Amputating*, p. 109.

The patient lying properly supported, the arm is to be raised from the side, and if the shoulder will allow it, into a horizontal position. As I have seen some ingenious persons professing as the patient's sharing in the motion of the operation, I put Guthrie and some other practitioners at thinking that the patient, if circumstances will allow, should be placed upon a table in the operation position. — *Norman for the Art. of Amputating*, p. 109. The strongest is to stand on the inside of the limb, apply the tourniquet as high as possible, and let the skin and muscles, which he is about to divide, be made tense by the hands of an assistant. The joint parts are next to be divided, as much of the limb being preserved as possible. The tourniquet is to be applied, the bone saved with the least possible loss, and the bleeding stopped in the ordinary way, care being taken to leave the joint, the rest of the ligature, which wound round the brachial artery. The wound is then to be closed so as to form a transverse line, the dressings are to be applied, and the patient put to bed with the wound a little elevated from the surface of the bleeding.

In tying off the arm, I entirely coincide with Mr. Guthrie with regard to the usefulness of dissecting back the artery, and, in consequence, a pain long ago removed by the celebrated Hagerstrom, their efficient attraction by an assistant after their complete division being quite enough. — *On Gunshot Wounds*, p. 204; but, as I have constantly retained Guthrie and others, in making the incisions through the muscles with the edge of the knife turned very obliquely upwards, it has not appeared to me necessary, after cutting down to the bone in this manner, to clear away the soft parts from it to the extent of an inch and a half or two inches higher. Instead also of attempting to perform the circular oblique incision through the muscles with our stroke of the knife, the obliquity to which have been noticed in the oblique or amputation of the thigh, I have made it a rule to divide the huge biceps muscle as soon as the integuments have been cut and removed, and of tying it fully round before the division of the rest of the soft parts is begun.

If the shoulder should require the arm to be taken off at its upper part, there would be no room for the application of the tourniquet. Here, instead of putting a compress in the axilla, and having it bent freely upon the axillary by a splinter, as advised by Sabatier, it is more eligible to make pressure on the artery as it passes over the first rib, of which method I shall speak in tracing the operation at the shoulder-joint. With a straight incision the surgeon is to make a transverse incision down to the bone, a little above the lower extremity of the deltoid muscle. Two other incisions, increasing

made along the front and back edge of this muscle, now form a flap, which is then detached, and reflected. Lastly, the end of the soft parts of the limb are to be divided by a circular incision made on a level with the base of the flap, and the operation finished like a common amputation.—*Neuberg, Midwifery Operations*, t. 2, p. 373, &c. ed. 2.

As a matter of choice, and not at all of necessity, the arm may be amputated with two flaps, one anterior, the other posterior. The first should be formed of the skin and muscle, and be three or four inches in length; the other is to be of the same size, and composed of the muscle and integuments. The muscular flesh close to the bone is now to be divided all round, and the arm freed. When preferred due to the common method, and adopted in most cases, the vein is the end of the bone always covered, that a portion of it is impossible.—*Practische Anweisung zur Chirurgischen Operationen*, p. 46.

When the arm is injured very high up, Baron Larrey gives an account of the following plan to preserve a clean stump, maintaining the upper end of the humerus; but, says he, if this bone cannot be divided at least on a level with the tendons (insertion of the deltoid), the stump is extended towards the ligament on the posterior margin and inserted there; the ligament on the muscle towards the humeral process of scapula; joint pain and nervous twinges, often ending in tetanus, are prevented; the stump refuses to heal; and, in the end, the limb is fixed by adhesions to the shoulder, so that this portion of the arm remains altogether useless, and renders the patient liable to accidents. "I have seen (says Larrey) many officers and soldiers, who on these accounts, were very glad they had not undergone amputations at the shoulder."—(*Mém. de Chir. Mil.* t. 2, p. 52, 403.)

Mr. Goulin also states, that when amputation by the circular incision is attempted at the insertion of the pectoralis major, the bone will generally protrude after a few days. However, he entirely disavows from Larrey respecting the necessity of making at the last, at the shoulder, and perfects using it from half an inch to an inch and a half below the insertion of the humerus, in the state of the injury may require. Two incisions are to commence, one of two finger-breadths below the axillary; and the other one it is to be extended directly across the outer side of the limb, till it meets the lower point of the other wound. "Then the outer part of the arm is cut by a circular incision; the upper in the same manner as it sometimes is in removing the limb at the shoulder-joint. Without detaching the skin from the muscles there are cut through. The soft parts are held out of the way of the knife; the bone is sawed; the vessels secured; and the flaps brought together, so as to form a flap from the axillary (continued).—(*Practische Anweisung*, p. 337, 403.) I am sensible of opinion, that, in the description of cases referred to, either this method, or Sabatier's operation should be preferred to the removal of the whole limb at the shoulder-joint.

Dupuytren sometimes amputates at the elbow joint, but as the stump is not much useful, then when the operation is done a little higher up, and the wound is frequently long in healing, the method appears hardly to merit a description.

AMPUTATION OF THE FOREARM.

The wrist usually, with respect to the place for making the incision, is to cut off at least of the limb as possible. This fact is perfectly established, though it is true that Larrey, in consequence of his mode of dressing the stump, has not experienced success in his amputations done in the middle part of the forearm. The forearm is to be held by two assistants, one of whom is to take hold of the elbow, the other at the wrist. The tourniquet is to be applied to the lower part of the arm, and the assistant holding the arm should draw up the integuments, so as to make them taut. The circular incision is then to be made down to the fascia; from there no more skin is to be detached, reflected, and turned, as is necessary for exposing the ends of the bones, and the muscles are to be cut on a level with the reflected skin, the limbs being at the same time drawn slightly upwards. As many of the muscles are deeply situated beneath the outer bones of the forearm, too much attention must be paid to dis-

secting all of them, with a double-edged knife, into dorsal between the radius and ulna.

The soft parts are to be preserved from the saw by a flesh extensor. It is generally recommended to saw the two bones together, for which purpose the instrument should be placed in the utmost state of position. As the radius of the lower part of the forearm is longer than the ulna, it should perhaps be sawed through first, the latter bone, in consequence of its connection with the humerus, being better adapted to bear the weight of the arm.—(*Avicenna Op. Chirurgia*, p. 124.)

The inner, radial, and two intermediate arteries are those which usually require a ligature.

Goulin reflects the forearm by making a flap from the third to fourth of the limb, and then extending the wound across the middle.—*Neuberg* (in *Practische Anweisung chirurgische Operationen*, p. 378, &c. the Berlin, 1814.) Mr. Goulin makes two flaps, one in front, the other on the back of the forearm; but, above the middle of this part of the limb, he prefers the circular incision.—(*Op. Chirurg. Wundst.* p. 334, 374.) Dr. Brown also expresses the opinion of separating the tendons, so as to make two separate flaps (*Principles of Military Surgery*, p. 203, ed. 3.) which is the method recommended and pursued by Goulin.—(*Practische Anweisung chirurgische Operationen*, Heft 1, p. 52.) Larrey also operates in this way in the lower third of the forearm. These flaps, instead of the forearm, are rather proceeded at choice than of necessity; for I have seen this part of the limb removed in almost all instances by the circular incision, and can hardly remember a case in which the sawy flaps were badly. In making the lower flap, the radius and ulna are not necessarily in danger of being wounded higher up than the point where they are quite cut through, as Mr. Goulin readily acknowledges; an accident which I think might give rise to a great deal of trouble.

With respect to Larrey's preference in amputating in the fleshy part of the forearm, though the real would admit of the operation being done much lower, I need only say, he would find no reason for this choice were he to practice again by the first incision at every opportunity, as is the custom in England.

The hand may be separated at the joint of the wrist whenever the disease does not extend too high, and a flap can be made of the integuments of the back of the hand. Informed thinks such an operation sometimes preferable to amputation above the joint.—(*Neuberg, Chirurg.* t. 2, p. 360, ed. 4.) Evidence seems the flap from the palm. The circumstances of the case should of course judiciously determine the choice. The amputation may also be done by the circular incision.

AMPUTATION AT THE ELBOW JOINT.

The very idea of this formidable operation has a long while checked the hand even of the most ready advocate for the use of the amputating knife, and every mind shuddered at so extensive a mutilation. Still, it could not be denied, that the chance of saving life occasionally depended upon a submission to the greatest temporary suffering, and that without the most rapid of amputations, the preservation of the patient was totally impossible. Doubtless an amputation at the hip appeared, both as respect to the magnitude of the part of the body to be removed, and the extent of the wound caused by such removal, the most formidable nature of amputation at length began to induce surgeons to view more dispassionately a scheme, at which the mind at first naturally recoiled.—Mention is the earliest practitioners who made this severe operation the subject of anatomical question (*Opusculum de Chir.* t. 1, p. 178, 179, 180, &c.) and in the year 1779, two essays on the same topic were communicated to the Royal Academy of Surgery at Paris, by two of its pupils, Voisin and Pottier. In 1782, Ravaton resolved to have performed an amputation at the elbow-joint in a case of gun-shot fracture of the humerus, radius, and neck of the ulna-bone, but was prevented by the opposition of other surgeons.—(*Flat. d'Anat.* p. 355, &c.) In 1785, the propriety of amputating the operation was urged by Alauzet.—(*Ann. Chir. Hist.* t. 2, p. 302.) At length, the Royal Academy of Surgery at Paris thought the subject highly deserving of further investigation, so it appointed a series of its members, that there were circumstances under which its performance might be advisable. In the year 1790, they therefore proposed the following

question, as the great point subject; in the case in which amputation of the hip-joint should appear to be the only resource for saving the patient's life, no determination whether the operation ought to be practised, and what would be the best way of performing it? No satisfactory decision having been arrived at, the same subject was proposed in 1793. The application of the Ankyer was now confined on a paper written by Barthe, in which the propriety of amputating at the hip-joint was defended, and some of the cases demanding the operation specified. If, for instance, a cancerous, or any other indolent tumour arose, had earned off or crushed the thigh, so as to leave only a few joints to be cut in making the necessary amputation, he thought a surgeon might not so hesitating about doing it. The same author considered that a sphacelus, extending to the circumference of the joint, and destroying the greatest part of the surrounding flesh, might also render the operation equally necessary and easy.—*Mémoires de l'Académie de Médecine*, t. 2, p. 271, &c. Cases were also adduced, where the surgeon completed the amputation of the dead parts with a knife. However, this cannot be considered as amputation of the hip-joint. Resolving a few dead tissues was a thing of no importance, in regard to the likelihood of its creating any bad symptoms. The proceeding, in fact, seems to me to have no analogy at all to the ordinary operation of taking the thigh-bone out of the socket. It is quite a different thing, where the operator has to cut through parts which bleed profusely, and are endowed with life and sensibility.

In addition to the remarks by Barthe, thirty-three other essays were added to the collection, the majority of which were filled with arguments in favour of the operation; and, besides these productions, two other memoirs were published at Paris, one by Guérinard in 1798, expounding a new method of operating, and another by Mouton (see *Ann. de Médecine*, in 1799), in which, says Professor Thomson, the operation is very aptly considered in all its different particulars.—*Atlas made in the Mil. Hospital in Belgium*, p. 699—700.

Some of the best surgeons of the last and present century condemn the proceeding. The following are Mr. Pott's sentiments: "M. Blandin and M. Tison are the only people whom I have met with or heard of who profess, who speak of an amputation in the joint as being an advisable thing, or as being preferable to the same operation in the thigh." After a discussion is two, he continues: "that amputation in the joint of the hip is not an impermissible operation, although it is a dreadful one! Every well-know, I cannot say that I have ever done it, but I have seen it done, and am now very sure I shall never do it, unless it be for a dead body." The parallel which is drawn between the operation and that in the shoulder will not hold. In the latter it sometimes happens, that the disease is confined to the head of the femur, and that the capsule is perfectly sound and unviolated. In the case of a carious hip-joint, this never is the fact; the surrounding vessels, and parts about, are always more or less in the same state, or at least in a disordered one, and an infected mass frequently runs the parts within the pelvis, &c.—*Pott on Amputation*.—How it may be remarked, that Pott was right, inasmuch as the operation is hardly supportable any more of the hip-joint, but wrong in not perceiving, that, ought still to vary alone, it might be proper for others. Callisen had difficulty in supporting any circumstances in which the operation should be undertaken with hopes of success.—*Ann. Chir. Hist.* p. 115, t. 3, 1845, 1846. And Richardson thinks, that indeed the task is nearly equalled by the disease at accident, a previous attempt should always making the attempt.—*Newcomb*, &c., p. 101, ed. 4.

It is a remarkable fact in the history of surgery, that an operation which had been invented in France, and gradually worked up to such had been written in that country, should have been first actually put in practice in England. It has been advanced (says Professor Thomson), that the operation was performed in London by the late Mr. H. Thomson, surgeon to the London Hospital, and that he had first been here his operations to which Mr. Pott alludes.—*Atlas made in the Mil. Hospital in Belgium*, p. 704. At all events, whether this was the original case which Mr. Pott saw or not, the example referred to by this distinguished surgeon is the earliest instance of the opera-

tion being actually performed. It was even repeated in two countries before it was ever practised on the continent, as far as can be made out from the records of the profession; for it was performed by Mr. Ross, of Northampton, upon a girl between eleven and twelve years of age, in a case of diseased hip; a case in which I am now considerably satisfied that it ought never to be attempted, for the reason laid down by Mr. Pott. In fact, Mr. Ross, after removing the head, found the acetabulum, and all the adjacent parts of the osseous structure, cancerous. But the experiment was here rendered still more hopeless by the patient being consumptive. Yet with all these disadvantages, the girl lived till the eighteenth day from the operation, and after death her lungs were found to be a complete mass of disease, one of them being totally reduced to matter.—*See Thomson's Med. Communications*, vol. 6, p. 247, 2vo. Lond. 1798. Larrey performed this operation twice in Egypt; and once while he was serving with the French army on the Rhine. He was encouraged to make these attempts to give his patients by the consideration that he had already preserved some lives by separating either both thighs, both legs, or both arms, or removing the humerus at the shoulder-joint. Larrey has also the true merit of having first done the operation, in the only description of cases in which perhaps (with the exception of bad examples of nervous or the highest part of the femur) it might ever be performed; viz. granulated pyrexia of the head, neck, and upper part of the breast, with or without injury of the femoral artery, or where the limb had been cut first away by a shell or cannon-ball, too high up to admit of amputation in the ordinary manner.—However, he also regards as fit occasions for amputation at the hip-joint circumstances in which, from gunshot violence, the first is seized or threatened with gangrene nearly up to the hip.—*Mémoires de Chir.* Mil. t. 6, p. 185.

Seeing as the operation is, Larrey contends that it is an act of humanity, if it ever in the course of saving lives which are in danger, and to argue that it is justifiable by the old maxim of Hippocrates, "Ad extremam morbois curam remedia." To the chief objections which have been made to it, he replies, 1st. That the wound is more alarming than dangerous. The Cassean operation (says he) has been successfully performed on the living femur, and is still recommended by many practitioners. 2d. As to the principal source of the disease (Hospital), has successfully removed a suppuration every of considerable size. Examples are recorded of the arm and supple being torn away, and the patients soon recovering. Besides, the supple has it in his power to lessen the wound produced by the operation. 3dly. The dangers of locomotion may be obviated by the assistants temporarily placing their fingers on the femur of the cut vessels, with ligatures can be applied.

In confirmation of his sentiments concerning the propriety of the operation, Larrey adverts to a fact reported by Marsini, where a soldier had both his legs amputated very high up, and who both his arms to near the shoulders that he could hold nothing in his hands. Yet, notwithstanding he was, he enjoyed good health.—*Opuscules de Chir.* p. 145. And Larrey, in his own work has recorded several instances in which the whole of a limb was removed, or more than the halves of both the upper or lower extremities of the same subject, without any fatal constitutional disturbance.—*Mémoires de Chir.* Mil. t. 2, p. 178—181. One of his patients above alluded to survived the operation a week, at the end of which he was carried off by the phlegm; and the others died, after being convalescent in a very happy manner, during the previous march of recovery.—*See Relations de l'Hôpital de l'Armée d'Orient en Egypte*, &c. p. 320, 3vo. Paris, 1801. At the battle of Wagram, Larrey operated at the hip-joint on two soldiers of the imperial guard, under very disadvantageous circumstances; and the wounds were healed in a few hours.—*Mémoires de Chir.* Mil. t. 2, p. 314.

Larrey lived to operate as follows: he began with making an incision in the neck of the original artery in the head of the groin, and after carefully dividing the nerve, which is now, externally situated, he tied the vessel, with the use of a semicircular curved needle, as closely as possible to Pott's ligament, in order that the ligament, which was placed above the origin of the circumflex artery and the profunda, might remove all interference from the bleeding

which might otherwise happen from such numerous lesions. This being done, a straight knife was perpendicularly placed between the tendons of the muscles attached to the tracheal anastomosis and the bone of the neck of the femur, so as to bring into its point at the back part of the limb, or in a diametrically opposite situation to its first extremity; and now, by drawing the knife obliquely upwards and downwards, a flap, which was not to be too large, was made of the soft parts of the inner and upper portion of the limb. This flap was now drawn towards the acetabulum by an assistant, and the articulation was brought into view. The vascular artery, and some branches of the venous field, necessary for making the flap, were immediately tied. The thigh was now put into the state of abduction; the inner part of the articular ligament was freed from its position, was divided, and the joint exposed. The ligamentum pectus was then cut, and the bone disarticulated. The knife was now brought to the outside of the great trochanter, and an external flap formed of the soft parts, equivalent to most that might have been made at the neck of the limb. In proceeding through the operation, Larrey secured, as soon as they were divided, the obturator arteries, and several branches of the profunda, gluteal, and ischiatic arteries. The two flaps were brought together and kept in this position with strips of adhesive plaster, and a suitable dress bandaged.—See *Mém. de Chir. M. E. V.* p. 146–148.

In the Russian campaign, Larrey had two more opportunities of operating at the hip-joint. In the first instance he operated upon a Russian at Witepsk, whose thigh-bone was broken to pieces by the tracheal anastomosis, and the soft parts of considerable thickness of the limb destroyed. This man was as favourable as possible until the 23d day from the operation, the parts being healed except at two points where the ligaments had been lacerated; but, unfortunately, a quantity of puriform matter declared from some neglect or mistake; and the patient on the 26th day fell a victim. The second operation was done on a French dragoon, at the battle of Moscow, who was afterwards soon perfectly cured by the same operation at Orléans, who received his wound, and made a report of the fact to Larrey himself.—See *Mém. de Chir. M. E. V.* p. 25–26, 31, 32, Paris, 1817.

In 1815, M. Botta, surgeon to the Hôpital des Enfants Malades at Paris, amputated at the hip-joint in the manner of Larrey, except that he only exposed the artery at the groin, and did not begin with tying it, a method to which Larrey himself now gives the preference.—See *Mém. de Chir. M. E. V.* p. 431. The patient was a child seven years old, and the case a diseased hip. The patient got well of the wound, but died of scurvy three months afterward. The cavity was found full of fungus flesh, and the os pubis was carious. As the latter was always exposed in the diseased hip-joint, the whole of the disease did not admit of removal by amputation, and consequently the strongest advice never to do again.—See *Journal, Dissection* &c.

The plan of operating adopted by Botta is corrected, I believe, by all surgeons of the present day, better than that formerly adopted by Larrey, inasmuch as the os pubis and unnecessary preliminary exposure of taking up the artery in the groin, instead of simply compressing it against the os pubis, was omitted. Coming down to the artery as a preliminary operation for exposure, is doing a useless operation, and putting the patient to needless suffering; it was the earliest method, having been proposed by Volkmann and Pott, who was the first proposer to, prove the artery against the os pubis, instead of cutting down to the vessel. I am not at present aware, and I never find it has been publicly recommended by Mr. Abernethy, in his various published lectures, for the last thirty years; it is a silly-two years ago I began to attend his course, and in the celebration of this operation, by the vascular method upon the dead subject, compression of the artery in the groin was then advised, and so I have used, not far from first class. Likewise it is said to compress articulation at the hip-joint upon the dead subject is not so common: the following is his method, as described by a military writer.—The patient of the patient lying on the edge of the table, and the limb being supported by an assistant, the operator places a line at such an angle, from the anterior and superior spaces between of the

bones straight down the thigh. From this point he carries another towards the knee, at right angles, so as to form a right angle. On the outer extremity of the last he places the point of a long pointed cutting, and pushes it perpendicularly downwards till it strikes against the head of the femur. Then passing it on the outer side of the bone, he makes a circular ligament of about an inch from the margin of the bone. He now cuts and draws, for an inch or two, in order to clear the great trochanter, and draws the external flap, now of five inches in length, by cutting down the line between the trochanters and bone. The femoral artery, which may now be seen, is in its compressed position between the fingers and thumb of an assistant, while the operator thrusts the knife in, and will at the same point as before, but carrying it on the inner side of the head of the bone, he forms a smaller flap on that side of the artery. He then, with the point of his knife, goes through the vascular ligament, divides the bone, and removes the limb by drawing the round ligament, &c.—See *Abernethy's Operative Surgery*, Lond. 1807, p. 151, &c.; also *Manuel, Méth. Op. vétér.*, vol. Paris, 1822. It is likewise said Mr. Pott, that as late as the present century some surgeons, and long since by the French, he will not injure the femoral artery, which cannot be divided till the bone is removed downwards. This is a great experience referred by Larrey in his operations; for before the surgeon cuts the artery, the assistant can amputate the limb into the bone and compress the vessel.

The disarticulation is accomplished as follows: the surgeon, holding the limb with his left hand, while the assistant holds steady the flap, makes a cut half an inch beyond the articulation of the bone-joint. The limb is then put in the position of abduction, the bone placed from the socket, the knife is carried round the bone, and the triangular and other remains of the capsule ligament are divided.—See *Ed. Med. Surg. Journ.* Nov. 18, p. 41.

A very similar method of operating was followed by Professor Van Walther.—See *Chir. and Walther's Journ.* Also *Andersson's Quarterly Journ.* vol. 1, p. 62.

This method was followed by Mr. Syme in the very interesting case in which he lately operated at the hip-joint for an extensive necrosis of the femur, where the neck of the bone was itself diseased. Unfortunately, when the wound was nearly healed, the patient became delirious, and died, at the beginning of the eighth week from the period when the limb was taken off.—*Op. cit.* p. 52.

Langebeck began the first incision on the outside of the femoral artery, and forms the external flap by extending the wound towards the tuberosity of the ischium. The knee is then inclined towards, and the head of the femur disarticulated, after which the limb is moved to the inside of the thigh, and the inner flap made.—*Ed. Med. Surg. Journ.* 1, p. 4, p. 52.

When conversant with the artery in Holland in 1804, I missed the line Mr. Cole in his performance of this operation. The plan adopted by him is the same as that which has been taught by Mr. Abernethy in his lectures, for more than thirty years. The flow of blood through the femoral artery was stopped by compressing the vessel in the groin with the handle of a key covered with lard. The thigh was then compressed as high as possible, above the tracheal anastomosis. The femoral artery was immediately secured, and afterward every other vessel requiring ligature. An incision was now made directly on the os pubis, and the head of the bone removed with the utmost facility and expedition. The patient had even less blood than in any ordinary amputation, and the wound required of being brought together with adhesive plaster in the best manner possible; so as to represent a transverse scar. I am sorry to add, that the patient lived only till the following day. In an *anecdote* case of fracture of the upper part of the femur by a grape-shot, where the operation had been delayed too long, the whole limb being surrounded with matter, and the upper end of the bone projecting through the back of the neck, I ventured to perform the same operation at Oudenhoorn in Holland, a few days after the month of August of 1800; and here happened what had often occurred; immediately the soft parts had been divided, as the bone was broken to pieces, the limb came off, leaving the head of the bone, the tracheal anastomosis, and

A small piece below them projecting. Had not the man appeared in a very bad way by the time the vein had been secured, I should now have removed the head of the bone; but the shock of the operation was such that he survived it but a few minutes, though scarcely any blood was lost. The result of operating by the anterior incision is preferred by Gosselin, who unknowingly considers it as a new method.—*Nature* for Dec. 13th, 1865, p. 115. It has also been proposed by Mr. Velin, with the modification of having an inch or two of the bone projected, which is done without giving any additional pain, by dissecting off the soft parts below the first incision drawn in the line. This projecting piece is intended to serve as a lever, with which the head of the bone is to be got out of the canal.—*Edinb. Med. and Surg. Journ.* vol. 2, p. 105. I especially wish to mention that I do not regard it as an important practical improvement; 1st, because in almost all cases, where the operation is necessary, the bone is so fractured that it divides in a steady mode by the injury; 2dly, because the scheme is unnecessary; 3dly, as Dr. Davis's case, where I assumed, the head of the bone was fractured from the articulation with the osseous tibia by merely making an incision over that point, cutting the ligaments, and drawing upwards of the small piece of bone immediately projecting. In fact, it is a pure scientific, requiring this operation, occupying a few minutes of spreading exposure from wounds, the bone is usually broken too high for Mr. Velin's method to be practicable. With the same view of facilitating the exit of the head of the bone from the canal, Gosselin, p. 117, recommends dividing the transverse ligament which completes the basis of the violence and inferior side of the socket. From my having once used one of the first antiseptics in London, with a powerful pain-reducer, and the whole length of the anterior incision for a lever, sufficed for nearly half an hour before I could dislocate the head of the bone, I suppose Gosselin's system worth mentioning.

Mr. Ashley Cooper suggested the operation by making an incision just above the patellar ligament, a little on the outside of the femoral artery. The wound was then carried obliquely down towards and outwards to the back of the thigh, about an inch of the way down it, from which point the knife was turned in the opposite direction, obliquely upwards and inwards to meet the first incision, so as to form an elliptical curve. The femoral artery, being now divided, was immediately tied. The muscles were next cut through, another artery wound, and the bone taken out of its socket. Only about twelve cubits of blood were lost.—*See Lancet*, vol. 2, p. 10, &c.

The following method is recommended by Mr. Scott, 1861. The patient was to lie on the opposite side of the body to that on which the operation is to be done. The femoral artery is to be compressed. The surgeon, standing behind the limb, is to put the thumb in the flexor of his left hand on the great trochanter. With the right he introduces the point of the knife perpendicularly over this process, and then depressing the handle, carries the incision forwards and upwards near the patella below the groin. He then curves the knife round the limb, cutting as deeply as possible, and bringing the knife at length up to the point from which the wound commenced. All the muscular fibres are fully divided by this first incision; still below the limb must generally be worked again, not the first stage of the operation can be completed.

For the purpose of getting at the vessels, the sides of the wound must be kept apart, and any transverse fibres not yet cut, be divided. As soon as it is performed, it is to be cut through perpendicularly on the head of the femur. The limb is now to be raised, the femur, and the bone divided, whereby the head of the bone is forced nearly out of its socket, and quite it completely as soon as the round ligament is cut, which is the easy part by which it is cut. The operation then raises the thigh bone, so as to make its head project, after which he cuts the rest of the capsule and transverse fibres, and completes the operation of the limb. When the operation is not the left side, the surgeon stands in front of the limb.—*See Bonald, in Methods Medicales, ou Nouvelle Methode pour amputer dans les articulations*, Paris, 1817, &c.

The variety in the mode of operating is now very considerable. Were I to offer a particular description

of every method, my limits would be greatly exceeded. It may suffice, therefore, to refer to Gosselin's *Journal* for an account of the plan which he adopted on the living subject; and though the case had not a fortunate result, the operation itself was very skillfully performed.

Several cases are now recorded, in which amputation at the hip-joint proved successful. The first was that under the care of Mr. Bowditch, attended to the same, on the 10th of December, 1811. The upper part of the thigh bone had been broken by a gun-shot near Meville, in Spain, the 22nd of December, 1811. Some time ago, the man was living at Spalding, in Lincolnshire, in perfect health.

The second successful operation was that performed by Larrey, at Wittepsk.

The third was done by Mr. Guistrie, in the *Nouvelles Annales* on a French prisoner of war, who completely recovered. This third is the example in which Mr. Ashley Cooper anticipated in the hip an account of a disease of the higher part of the femur. As the patient had formerly suffered amputation of the thigh, it was certainly not the sudden removal of every a quarter of him; but I cannot promise to say, any difference in the character of the process, and whether any result is connected with the circumstances.

In June, 1821, amputation at the hip was done by Professor Dieffenbach, at Nottmiller, on account of a tumor of the femur, and the patient was completely well in the following September.—*See Review Medical*. The operation was also performed by Dr. May, at New York, on the 7th of October, 1821, and the wound of the wound had healed by the 20th of November. This case was a bad fracture of the upper part of the femur, followed by abscess and disease of the bone.—*See Philadelphia Journal*, No. 9, vol. 3, New Series. The patient's age was favorable, as he was a boy of only ten years of age. At this period of life, the chances of recovery will always be greater than in adults, not only in consequence of the remedial power of nature being then prepotently great, but on account of the smaller dimensions of the vessel necessary for the purpose of the operation.

The following details of this case may prove serviceable to the profession, by showing that the operation may be advantageously attempted in a patient who would otherwise have speedily sunk under his disease. It is moreover interesting from the circumstance of its being the first instance in which it was ever successfully performed, and the first amputation at the hip-joint in this country.

George Bayle, a healthy boy, ten years old, broke his thigh about two days of its length from the hip-joint; two days after, sprains and bandages were freely and judiciously applied, which produced great distress, and were removed at the suggestion of the boy. Phlebotomy modification of Bonald's spirit was prepared by the physician then called in, who joined out to the father, previous to his amputation, a projecting point on the outside of the thigh, which was the extremity of the superior ligament, which by the improper pressure was nearly forced through the integuments. The bone being properly exposed, the long spirit was then applied.

About three weeks subsequent to this period another physician was called in, who recommended the employment of the inflated plexus, which was adopted, the bundle forming it having rests at the side. The boy stated that during his confinement in this inflated plexus for several weeks, he had an insupportable itching about, exposed the thigh on the inside just above the cord, which produced a situation requiring looking to the dislocated bone. If present pusillitas, however, that the skin was dried and peeling when it was struck against the pet and spread.

He was brought into the city of New York on the 7th of September, 1821, at which time we first saw him. His countenance was expressive of much anguish with a white tongue and loose pulse; his right limb was much enlarged on the outside, denoting a case of acute aneurysm. Some time it was hard and ungiving, was exceedingly tender, and when pressed gave excruciating pain. The swelling extended to the great trochanter, gradually diminishing towards the top of the thigh. Opposite to the greatest enlargement was a sinus, discharging a thin mucous fluid, leading to the middle of the thigh bone, which was perfectly carious.

During two weeks preceding his arrival in the city, medicines were administered with a view of allaying irritation, and improving him to the extent, his health and night sweats, notwithstanding, improved. As hemorrhages began to occur by the use of the ligatures, and all the symptoms became more, it was resolved to attempt at the ligatures as the only chance of saving the life of the patient.

On the 17th of October, 1861, the patient, after having passed a comfortable night, was placed upon the table of steel to be operated on. An incision was made over the femoral artery as it emerges from under the femoral arch, and the vessel secured by ligatures. While lying on the outside of the artery for the lower coarctation, the patient lost a vessel apparently not much smaller than the femoral artery immediately below the incision, continued as that in this case, the profunda femoris was given off above the femoral arch, as we occasionally find it. This vessel was taken up.

Ligature's ends were then introduced between the artery and bone, and carried through close by the back of the artery towards the tibial arch, thus forming the inner flap. The external flap was raised by pulling from without inwards. The hemorrhage from the veins and small arteries was considerable when the incisions were made, and arteries and veins were taken up; but comparatively little blood was lost during the operation, and the patient was put to bed shortly after it was completed. After the inner flap was cut, some of the vaginal abundance, expressing the lower trochanter, protruded from the head of the bone was not disengaged. In order to satisfy the doubts expressed, the bone was exposed through the lower trochanter, when it was found to be of the consequence of disease, being detached of portions on the outer side by towards the joint, and requiring to be removed, which was afterward done, as originally contemplated.

It is entirely necessary for us to enter into the detail of symptoms and treatment subsequent to the operation, as nothing occurred worthy of note, except various degrees of irritation of the stomach and water system, previous to the closing away of the ligatures. The treatment consisted in regulating the diet, and administering anodyne and tonic medicines according to circumstances.

On the 17th of October, eight days from the operation, two-thirds of the stump was healed by the first intention. Between the 17th and 21st of October, all the ligatures, according to custom, were removed; and by the 23rd of November the whole stump was effectually healed, and the boy had become fat and hearty. There can be no doubt but that this limb might have been saved without difficulty, had the proper treatment been instituted when the accident occurred. When it came under our charge, nothing short of the operation above related could have saved the boy's life.—*Amos.*

Another successful amputation at the hip was performed by Mr. Green; the disease commenced in the knee; but terminated in extensive disease of the thigh-bone, large abscesses, and dislocation of the knee, the leg being fixed in the bent position, and drawn under the thigh.—*See Med. Chir. Trans. vol. 12, p. 685.*

On the other hand, the failure of this operation are innumerable, through misadventure by surprise of operation and ability. Mr. Gifford, Dr. Keary, Mr. Brownrigg, Barnes, Larrey, Walther, Gosselin, Mr. Beale, Mr. Charabiel (Trans. of the Assoc. Physicians, vol. 2, p. 185), and many other military practitioners, have had opportunities of attempting at the hip without success.

A caution has been made, that out of twenty attempted hip-joint amputations, six have had a favorable termination.—*Chelius, Fland. der Chir. b. 2, p. 162.* According to my observations, this account is rather too favorable.

No one can expect, however, this operation not to fail in a large proportion of the cases in which it is attempted; that must always happen, let it be done in the most skillful manner possible. Yet, as there are unquestionably some descriptions of injury, where life must be inevitably lost, if this proceeding be rejected, and experience proves that it sometimes succeeds, an important consideration is what cases are most proper for it. Here I am decidedly of opinion with Professor Thompson, that the operation is valuable in penetrating either gas, and when no other means

be suffered, are those in which the head or neck of the thigh-bone has been fractured by a gunshot ball, grasp, shot, or small piece of steel. Eight or ten such cases, where amputation could be done less than in the first instance, were brought in Vienna several days after the accident to Rouppey-op-Zoon, from the hospital was performed by myself at Quakenbush, and not one of these patients lived ten days after their amputation. In the single case of my personal care, I have never observed it succeed so much suffering, or suppuration as with profusion. From each limb, I should guess, that at least three or four joints, if matter were discharged daily. But amputation at the hip has been performed at first, some of these patients might possibly have been saved, at all events, I am certain that it was their only chance.

Larrey, as I have stated, thinks the operation proper, where the thigh has been shot off high up, or where the femur and soft parts near the hip have been broken, and extensively lacerated by a cannon-ball or piece of shell. Hence the operation, though perhaps the only chance, must almost always fail, because, as Professor Thompson observes, these injuries occasion a shock to the constitution, of which the patient mostly swells either immediately, or in a few hours.—*Amos, made at the Med. Hosp. in Belgium, p. 174.* The result of this observation I have corroborated at Mendenham, near Antwerp, at the headquarters of the French fleet in that port; a shell burst between the thigh of one of the guards; tore and lacerated two-thirds of the thickness of the upper part of the right thigh, broke the ascending ramus of the ischium; lacerated the perineum and scrotum; and fractured the higher part of the femur. There was no hemorrhage of consequence; but the exposed lacerated surface of the soft parts was immense, and the unfortunate soldier, who lay with his limbs standing erect, and bent of his intellectual faculties, sunk in the course of a quarter of an hour into a state of insensibility, and ten minutes dead in twenty minutes. However, there are some cases in which the patient, after dreadful laceration of the upper part of the thigh, are less depressed and overcome, and live several weeks; these strongly proving that the operation might be attempted. Many instances of this kind are related by Mr. Gifford.—*See Gun-shot Wounds, p. 128, &c.* Had and irreparable disease of the upper part of the thigh (the scapular hip, not any other example at which the pelvis is affected, may also require the performance of amputation at the hip-joint, as was recently illustrated in the practice of Mr. Home, of Edinburgh, and in that of Sir Astley Cooper. The case in which Mr. Carmichael attempted at the hip, was what we termed as osteomyelitis; the patient, a girl 16 years of age, died on the 15th day.—*See Trans. of the King's and Queen's College of Physicians, Ireland, vol. 2, p. 257, &c. and Vol. 2, p. 128.* Dr. Nott's case, already referred to, was one of fracture of the upper part of the femur, leading to disease of the bone and extensive abscesses. The disease, for which DePorch operated, was caries of the thigh-bone. The progress of the operation in desperate cases is now perfectly established.

ANATOMY OF THE SHOULDER-JOINT.

R. P. Le Drac performed the first operation of this kind, of which the particulars are recorded. It was in a case of cancer and necrosis, resulting from the middle in the neck of the humerus. Le Drac began with rendering himself master of the bleeding, for which purpose he introduced a straight needle and a strong ligature under the artery. This was passed from the front to the back part of the arm as closely to the axilla and bone as possible. The ligature then, including the vessels, the flesh surrounding them, and the skin carrying them, was tightened over a compress. Le Drac, with a straight narrow knife, then made a transverse incision through the skin and deltoid muscle down to the joint, and through the ligament surrounding the head of the humerus. An assistant now raised the arm and dislocated the head of the bone from the cavity of the socket. This allowed the bone to be raised with ease between the bone and the flesh. Le Drac then carried the bone downwards, keeping its edge always somewhat turned towards the bone. In the manner he gradually cut through all the parts, as he lay a little below the ligature. As there was a large flap, Le Drac made a second ligature with a curved

blood, which ligature included a great deal of flesh, the peduncular portion of which was cut off together with the first ligature, which had become useless.—*Obs. de Chir. 1. 3. p. 215. Paris 1781; and Traité de Chir. p. 265.*—*La Faye* (the son), who performed this remarkable case, does not state that the operation was a new one, and it appears from the *Recherches Cliniques* sur l'Anesthésie, &c. de la Chirurgie de France, and from *La Faye's* notes on *Hist. nat.* that it had been previously performed by *Morand*, the father.

Garengeot observes that the ligature might be applied by means of a curved needle, with sharp point; and in order to lessen the wound, he directs the insertion of ligatures at three finger-breadths below the incision, across the distal tendon, so as to form one flap; then a second one was made in the arsis; and after the second ligature had been applied, the two flaps were brought into contact.—*Traité de Chir. 1. 2. p. 232; Mém. de Acad. de Chir. 1. 2. p. 961.*

La Faye extended the incision one finger further. After placing the patient in a chair, and bringing the arm in a horizontal position, he applied, with a common bistoury, a trifurcate incision into the distal tendon, about a line below the elbow, four finger-breadths before the incision. Two other incisions, one in front, the other behind, descended perpendicularly to this first, and made a large flap of the figure of a T, which was then detached and turned up towards the top of the shoulder. The two ends of the incision, the remains of the superficial integuments, were pinned and well secured, and the capillary ligament, which was first divided. Now when the muscular wall had the lower part of the first flap, the last described flap turned up a lever of the bone, the head of the bone was easily dislocated. *La Faye* next carried the incision downwards, about the inner part of the arm, until he was able to feel the vessels, which he tied as near the axilla as possible. The separation of the limb was then completed a finger-breadth below the ligature. The flap was then brought down over the glenoid cavity, and the wound closed.—*Obs. Neurolog. Méthode pour faire l'opération de l'Amputation dans l'Amputation du Bras avec l'Omoplate*, par M. *La Faye*, in *Mém. de l'Acad. de Chir. 1. 2. p. 193, 180.* With respect to *La Faye's* method, it is useless to make a comparison between him and *Larrey*; the latter, though generally accused, is the author of nothing strange by the first intention, is an advocate for this practice after long and repeated operations, as *La Faye*, who was fearful of laying down the flap after amputation of the leg, had no such apprehensions at the shoulder.

La Faye's method as yet regarded as one of the worst appeared when the state of the soft parts well suited it. But it is almost to think of applying any one plan to all the various states in which the injured or diseased limb may present itself. It is advised by *Larrey* himself, when a wound extends through the upper part of the arm, breaking the bone, and exposing the soft parts. Here, says he, it would be impossible to force an anastomosis and a powerful flap, for the soft parts in these situations have been destroyed. On the contrary, when the distal is short, *La Faye's* plan is inadvisable.—*M. de Chir. 1. 2. p. 971.*

The advantages of *La Faye's* plan are obvious. As only one ligature was applied, the patient was saved a great deal of pain; the flap connected with the arm, was capable of covering the whole surface of the wound, and was more easily applied and kept on the stump than the covering of the two flaps which *Garengeot* recommended; and the discharge went a ready issue downwards.

Mr. S. Wilson recommended the following plan: "The patient was lying flat horizontally, make an incision through the connective adipose, from the upper part of the shoulder across the humeral tendon down to the arsis; then turning the limb with its edge upwards, divide the muscle and part of the tendon, all which may be done without danger of wounding the great vessels, which will become exposed by these incisions. If they be not cut with ease of the distal muscle, and carry the arm backwards. Then, with a strong ligature, having tied the artery and vein, pin the muscles together through the joint, and carefully divide the vessels at a considerable distance below the ligature; the other small vessels are to be secured, as in other cases."

* In doing this operation, regard should be had to the

artery as much as possible, and to the situation of the processes anastomotic, which, projecting considerably beyond the joint, an ordinary operator would be apt to cut upon.—*Observations of Surgery.*

Brookfield used to press the artery against the first ap. The member begins at the lower of the arm by the edge of the distal tendon, as high up as where the processes pass over the axilla in its insertion into the humerus. Passing through the anastomosis and vessels, he continued his incision obliquely downwards and outwards, as far as a little below the insertion of the distal tendon. Then, coming up the humerus transversely for a small space, he continued dividing the wound was next extended to the external part of the arm as high as the spot of the anastomosis in the axilla. The flap thus shaped, which raised from the humerus, was intended to fill up the axilla, after the removal of the limb. *Brookfield's* axilla incision began at the anastomosis, and being carried through the vein and arterial cord to the bone, terminated in the semicircular incision above described, and it was so guided that it left the outer portion of the divided flap larger than the inner one. Hypothetical then passed his knife under the lower edge of the internal half flap, and dissected it up as far as possible. The border of the posterior muscle was thus exposed, under which he now passed his left forefinger, which, acted as a retractor, is a protected external boundary. With this he now divided the attachment of that muscle to the humerus. If the vessels were not now sufficiently brought into view, he cut through the outer end of the humerus, and tied them artery and vein each with two strong ligatures about half an inch apart. The vessels were then cut through in the interspace, and the nerve was divided much higher than the artery. The external flap was now raised sufficiently to expose the joint; and the nerves and capillary ligament having been cut through in the upper and lateral parts, the humerus slipped out of the glenoid cavity, and the whole of the arm was carried a little backwards. Lastly, the ligatures and vessels being held out of the way, the soft parts towards the axilla were divided in a semicircular direction.—*Chir. Obs. and Cases*, vol. 1. p. 218–220, 1780. London, 1781.

The necessary inflexibility and easy fall, contrary to *Brookfield's* method have long constituted him a the approach of modern operators. The diameter of the flap into two portions, its extraordinary length, and the partial division practised to get at the artery, were among faults in the operation.

In 1778, *Almon* appeared at the shoulder-joint as follows: The subclavian artery was exposed by the fingers of an assistant. An incision was made about a finger's breadth below the anastomosis, and carried through the tendons all round the limb. The distal and posterior muscles were then obliquely divided up to the capillary ligament. The border of the incision and the capillary ligament upon the anterior and posterior part of the joint were now cut through. One of the circumflex arteries, which had a good deal, was tied. The great pedicle artery, the rest of the vessels, and all the other parts except the vessels and nerves were then divided, but previously in cutting the vessels a trifling ligature was put around them. Thus the separation of the limb was completed. The muscles of the vessels were drawn on and tied, and the temporary ligature taken away. Lastly, the sides of the wound were brought together, so as to make a transverse line. (Great, seemingly not to be neglected, as the operation by the circumflex vessels does not obliquely upwards had been practised by *Almon*, mentioned as a new proposition. It was done, after operating at the anastomosis, the patient was quite well in three weeks, and with his particular set of habits which he was, and which is much towards to point, he pretends to be able to make the oblique incision through the muscles all round the limb with ease every. Of course he is very careful to make pressure on the artery, both with *Mohr's* compression applied under the axilla, and the finger of an assistant above it.—*Obs. Neurolog. Méthode pour faire l'opération de l'Amputation du Bras avec l'Omoplate*, par M. *La Faye*, in *Mém. de l'Acad. de Chir. 1. 2. p. 193, 180.* In proof of the possibility of making the oblique incision quite easily with and without of his particular habit, he appeared a former subject, did the operation, and closed the wound to be drawn from all time.—*See Faye's* in *his Works*.)

In 1780, P. H. Dard published at Göttingen a description on amputation of the shoulder. In the first a

trousers were also detailed by Chalmers.—*Harley's Rep. Clin. &c.* 2, p. 754.

AMPUTATION OF THE WRIST OF A WOMAN.

In a letter to Mr. Pott, dated 17th, Mr. Park, surgeon to the Liverpool Hospital, made the proposal of totally amputating every diseased joint, by which the limbs might be preserved, with a share of motion that would suit a woman to be very useful.

Mr. Park's scheme, in short, was to remove entirely the extremities of all the bones, which form the distal joint, that is, the wrist, as much as possible of the regular ligament, and to divide a part by means of a saw, of the tendon of the flexor to the radius, when the operation was done on the right; and to perform in the same way on the left, when it was done on the elbow; so as to leave no more articulation in these situations.

In order to keep whether the postural vessels could be avoided without much difficulty in the exposure of the bone, Mr. Park made an experiment on the dead subject. An incision was made, beginning about two inches above the upper end of the radius, and extending about an inch below on ulnar part. Another cut was made within the articular ligament, immediately above the point, where in the bone, and finally half round the shaft, the ligament was all cut off. The lower angles formed by these incisions were bound up as far as they were the regular ligament; the tendons of the flexor were cut off; the upper angles were bound up, so as to form a dome; the head of the flexor, and a small swelling in the point of the posterior part of the bone, immediately above the articulation, were being taken to keep out of the fat pad of the point of the instrument (this done on the bone at the wrist). The cutting being withdrawn, an elastic bandage was introduced at its place, to guard the soft parts while the flexor was raised. The head of the bone, thus separated, was carefully dissected out; the head of the ulna was then with care raised up and saved off, and as much as possible of the regular ligament dissected away, leaving only the posterior part covering the vessels, which on examination had been in very little danger of being wounded.

The old artery was on the elbow; a single longitudinal incision was made from about two inches above to the same distance below the point of the dissection. The integuments having been raised, an incision was made to divide the lateral ligament, and to divide the joint; but this being found sufficient, the dissection was stopped off, after which the joint could be easily detached without any extensive incision, the lower extremity of the ulna having saved off, and preserved the bones of the radius and ulna. This appeared an easy work; but Mr. Park mentions the case well be difficult in a diseased state of the parts, and that a crucial ligament would be required, as well as dividing the tendons above the condyles, in this way done with respect to the distal bone.

Mr. Park first operated, July 5, 1798, on a strong robust man, aged 22, who had a diseased knee, of ten years standing. The painful sufferings were daily increasing, and his health declining. Mr. Park wished to avoid cutting the massive incision, thinking that, after cutting the parts, he could effect his object by the use of a small saw; but it was found that the difference between a healthy and diseased state of bone distressed him in this operation. Having by this way separated the joint, the transverse ligament made. The operation was finished exactly as the one on the dead subject before. The quantity of bone removed was very little more than two thirds of the bone, and rather more than two thirds of the shaft. The only artery divided was one of the from of the bone, and it ceased to bleed before the operation was completed, but the point of the bone still very freely. In order to keep the wound separate from putting ligatures, and the point of the vessels in a comfortable state, a few sutures were made. The dressings were kept and continued very much. The dressings were kept and continued very much. The dressings were kept and continued very much. The dressings were kept and continued very much.

During the recovery Mr. Park throughout the treatment. During the recovery Mr. Park throughout the treatment. During the recovery Mr. Park throughout the treatment. During the recovery Mr. Park throughout the treatment.

passage which formed. On the other hand, however, the first attempts were not at all successful. But the patient was obliged to keep his bed, and on the 10th he was moved, and it was every day better, and the pain was less. The next afternoon went to sea, and did his duty very well.

Subsequently to the publication of the letter to Mr. Pott, another section of the knee was done by Mr. Park, on the 10th of June, but the wound was almost healed, as the patient died on the 12th of October, and then died.

In 1802, P. F. Moreau presented to the French Academy of Surgery a memoir, proposing the removal of various parts. It only seems necessary to notice here the difference in Moreau's plan of separating from that adopted by our countrymen. Moreau, the son, who has published two accounts, observes, that the dissection of Moreau's operation, as two months every purpose; and to denote Mr. Park's direction to remove the ligament, if this be first from above, at least from below. Moreau never operated on the elbow as follows: with a drawing pin, he cut down to the sharp edge on the edge of the upper condyle of the ulna, about two inches above the articulation; and, directed by the eye, he carried the incision down to the point. He did the same on the other side, and then continued the two incisions by a transverse incision, which divided the skin and the tendon of the flexor, immediately above the articulation. The flap was elevated from the bone, and held out of the way by an assistant.

The flaps which adhered to the bone of the bone above the condyles was now separated, care being taken to divide the part of the instrument with the finger of the left hand, and when the handle of the scalpel could be placed through between the bone and the bone, Mr. Moreau directed it to remain there, and moved the bone through upon it. The removal of the part of bone was now finished, by detaching it from all its attachments. The removal of the bone of the radius and ulna remaining to be done, with other difficult, and the first flap being insufficient, it became necessary to make another. The lateral incision, at the outer side of the arm, was extended downwards, along the external border of the upper part of the radius. The head of the radius was separated from the surrounding parts; its connection with the ulna being cut, and a small piece was introduced between the bones, in order to keep the bone out of the way of the saw. The incision was placed through, near the insertion of the biceps, which was particularly preserved. Some remaining osseous parts, fixed with pins, were removed with a gouge. The ulna was now exposed, by separating the intermuscular on the inner side of the arm. Thus another flap was made, and detached from the back part of the forearm, and that portion of the bone which it was wished to remove. The bone being separated from every thing that adhered to it, and a strip of linen put round it to protect the flesh, about an inch and a half of it was saved off, measuring from the tip of the olecranon downwards. A few diseased osseous parts were taken away with the gouge. Two or three vessels were tied, and the flaps were brought together with sutures. In a fortnight this man became so well, that he was allowed to go wherever he pleased, with his arm supported in a case. The arm was at first painful, but it slowly recovered its strength, and the man could ultimately thrust arm and hold his plough with it, &c.

Seven months after another operation, performed in the same way as the preceding one, by Moreau the father, the patient was completely cured, and two years after this period the function of the forearm in the arm was very restored. In another case only the longitudinal incision and a transverse one were made, the flap being of considerable length. The patient got well in six weeks, and in three months was doing his regular work.

In all Moreau's cases, the flexion and extension of the forearm were preserved, which circumstance was highly depended very much on the insertion of the biceps not being destroyed. After the removal of the bone, however, the bones grew together.

Moreau gave a method of separating differed from his father's, inasmuch as the patient was in a supine position, and a sitting posture, and the os humeri moved before it was detached.

In a knee-case, Moreau the father operated as follows.—He made a longitudinal incision on each

sides of the thigh, between the vasti and the clunius of the leg, down to the knee. These incisions begin about two inches above the condyles of the femur, and were carried down along the sides of the bone till they reached the tibia. They were united by a transverse suture, which passed before the patella, down to the knee.

The skin was raised, but the patella retained in its being dissected, was dissected out. The skin was then laid, so as to bring the vessels of the femur into view. A line was drawn to cut them from the body of the bone before dissection there, every third adhering to their bed, where they joined the body of the bone, was separated as that piece like the fore-finger of the left hand was passed through in order to push back the skin from the bone while the saw was used. The bone having been laid, Moreau drew the cut piece to wards left, and easily detached it from the femoral ligament.

The head of the tibia was laid bare by an incision nearly vertical lines being made on the spine of that bone. The first lateral incision on the outer side of the knee was extended as far down as the head of the tibia. Thus were obtained two flaps which were laid to the flesh along by the interosseous space, and another incision the femur of the skin covering the inner surface of the tibia, which had been of necessity exposed before the saw could be applied.

Upon raising the outer flap, the head of the tibia was laid bare, and after being separated from its attachments was cut off with a small saw. The inner flap was then raised, and the head of the tibia having been separated from the patella, behind, was turned off.—(See Moreau's *Revue des progrès de la médecine* &c. in relation to amputations, *Annales de la Clinique*, Paris, &c.) Some physicians, however, in favour of the removal of diseased joints, have been published by Mr. Crumpton.—(*Dublin Hospital Reports*, vol. 4, p. 185, &c.) He has observed with success one knee and one elbow. Another amputator, only he is not known as a name, has twice having taken joints, and in which and otherwise having continued to the knee until the patient's death, three years and two months after the operation. Regarding the plan of operating on the knee he mentions that: "I am satisfied, from repeated trials on the dead subject, that the operation can be most safely and rapidly executed by separating the condyles from all their attachments previously to sawing the bone. As soon, therefore, as the flap containing the patella is turned upwards, the edge of the tibia should be carried round the condyles close to the bone, so as to divide all the ligaments which connect the femur with the tibia. The skin can then, with great ease be pushed backwards, and as much of the projecting vessels can be removed as the operator may think necessary."—(Vol. 4, p. 713.)

It does not appear necessary to insert in this work the account of cutting out the ankle-joint, an operation which will never be extensively adopted; nor shall I add any thing more concerning the mode of removing, in a similar way, the shoulder-joint. In treating of amputation in this volume I have already said enough, and whenever wishes for further information respecting this practice, must refer to Dr. Jeffray's work, entitled "*Notes of Experiments on the Joint*," Glasgow, 1804. This publication contains all that was then known on the subject. Dr. Jeffray has recommended a particular, and indeed a very ingenious, saw, for performing the above operation. The saw is fixed in a constructed wooden joint, like the chair of a wheel, so as to allow itself to be drawn through behind a bone, by means of a crooked handle, like a thread, and to cut the bone from behind forwards without dividing the soft parts. An experiment of this kind was executed in London by Mr. Richards, who was assisted in making it, by his disciples, the present Mr. Richards, of Bury-street. In placing the saw under a bone, its cutting edge is to be turned away from the bone. Blades are afterwards pushed to the instrument.

According to my notions of the treatment of diseased joints, nothing less than the patient's strength is an obstacle to the operation of the knee-joint. I am fully disposed to the propriety of preserving in an attempt to save the affected joint, Dr. Will's patient, greatly reduced by local symptoms, he also is removed from his bed and house as depends on the dissection of the whole of the knee-joint out of the limb? If some one should escape with life and limb preserved, would the bulk of

persons treated in this manner have the same good fortune? I cannot admit that the dissection of the whole of so large an articulation as the knee can be compared with the operation of amputation, in point of safety and utility. However, it is not on the difficulty of performing the former, that I would found my objections. As I believe that any man possessing a scientific knowledge of the anatomy of the joint might venture to perform the dissection. The principle on which I founded my opposition to the attempt to cut out large joints was the following:—1. The great length of time which the healing of the wound requires. Whenever I saw the case of Doctor N.Y. patient, well did that the operation was performed on the 2d of July, 1781, and that it was February 20th of the following year before all the violent fevers subsided and convalescence perfectly healed. This space of time is very greatly to be dreaded. Mr. Park describes the patient as delirious, restless, and gives no further particulars concerning the state of his constitution than that his health was declining. I venture little doubt, that if the operation of the knee had been performed in the usual healthy condition in which preparation for such a great operation, this case would not have afforded the illness arising from the operation. The only after case in which Mr. Park compared the knee joint dissection. In the operation related by Moreau there was, indeed, to be considerably added. This patient survived the first dangers consequent to an severe operation, and after three months' confinement, the patient was at such a state that Moreau observed he would be able to walk with crutches in another month or six weeks. The young man, in the same time, was attacked by an epidemic dysentery and died. On the 21st of October, 1782, Moreau occupied the knee-joint of a pregnant woman in the hospital at Grosvenor; but she died of labour on the 26th of the following February. He observes that the operation is much facilitated by removing the skin of the femur and tibia in their compound state.—(See *Ann. de la Clinique* &c. *Annales de la Clinique*, Paris, &c.) 2. Even supposing the extension of the knee to be followed by all possible success, is the advantage of having a quadruped, maimed, and half, in any other member, sufficiently great to induce any man to submit to an operation, beyond a doubt infinitely more dangerous than amputation? I think not. The practice is at present hardly included in this century; but I have every one and then of its being adopted at Paris, and Mr. Crumpton has thought a worthy of several. The difficulties of his operations, however, and tediousness of the after-treatment, and in particular the general course and formation of one of the two ligaments, as represented by himself, are sufficiently discouraging. No doubt, more limbs might be saved by this practice than by that of amputation, but many lives would be lost. On this principle I see no reason for preferring one mode to another. Many interesting observations on the extirpation of various diseased joints may be found in the above mentioned dissertation by Wacher, and in the analysis of it by Laingbeck.—(*Brit. Jour. de la Clin. & G. Gallien*, 1805.)

It is getting this part of the subject, I may just notice the interesting cases recorded by Mr. Bury of St. George's, which cut out several of the lateral bones, including the diseased surface of the acetabulum, and also some of the distal bones from a boy's knee, with complete final success. The dissection, however, was protracted, and great difficulty experienced in stopping it. Whether this last experiment merits admiration, I am not prepared to say; but, be this as it may, the fact merits attention.—(See *Med. Clin. Trans.*, vol. 11, p. 285.) Consult also White's Case in *Surgery*, published, *Mémoires politiques de l'Académie de la Clin. Paris*, 1779, p. 75; et *Mém. de l'Institut National*, vol. 5, 1795; *Revue de la Médecine*, &c. in *Revue des sciences*, &c. Paris, 1799. *Ph. Crumpton*, in *Dublin Hospital Reports*, vol. 4, 1827.

MODIFICATION OF THE STAPLER AND TOOL, AND PART OF THE CUT.

The best surgeons all agree with Mr. Sharp, that the amputation of the fingers and toes is most successfully performed in three articulations. With a common scalpel, the skin is to be cut through vertically, not exactly upon the joint, but a little towards the extremity of the finger, in order that a sufficient flap may

be preserved by covering the end of the bone. On taking away a finger from a natural bone, Mr. Hay recommends amputing the bone behind and with skin on each side of the joint, as a means of facilitating the separation.

In amputating the fingers and toes the operation is greatly facilitated by cutting thro' the joint instead of the bone. Having made an opening in the back part of the capsule, one of the lateral ligaments may easily be cut, after which nothing is to be done of the bone from being raised out, for the surgeon has only to cut through the rest of the exposed ligaments and ligamentous parts.

Some recommend holding a small bone-saw at an oblique to cover the bone; but this is quite unnecessary. If one be taken to hold the skin a little up, and to cut with Mr. Hay's finger-rover, the bone, as we saw in a small flap given little pain, I have generally preferred this method, though it appears at first nearly a matter of indifference which plan is adopted. In operating on the parts between the phalanges and metacarpal bones, a flap should always be made, either up the upper, or under part of the finger, or the thumb.

Although it is generally best to remove the fingers at the joints it is sometimes thought right, where the injury has perforated the joint and so near, to cut through the bone, instead of operating at the joint articulation.—See *Guidance in Gun-shot Wounds*, p. 264. The division can also be readily made with a cutting pliers.

It first happens, that the bones of the foot and fully part of the metatarsal bones are removed, in which case the leg need not be cut off, but only so nearly as the foot as is discoloured. A small opening now is here the most convenient. When this operation is performed, the hand and the remainder of the foot will be of great service, and the patient will be able to walk. Mr. B. Hay, in his book, has had to do with some such examples.—Op. of Surgery, chap. 20, sec. 2. Mr. Hay mentions this statement of Hay's concerning the impossibility of retaining the whole foot, when the metatarsal bones are cut, and every other part of the leg is saved, as the remainder of the foot is of importance in walking, the use of the ankle not being destroyed.

Mr. Hay describes a new mode of removing the metatarsal bones, which, on review, that has fully answered the expectations. By the first part I have seen a plan which method, which had not been previously described, though it may have been performed by others, since that by Mr. Hay himself, by the name of having first done it is required in the late Mr. Turner, of North Yarmouth, who did it with success about the year 1837.—(See *Philosophy's Pract. Dis.* p. 70.) Mr. Hay makes a mark across the upper part of the foot, to denote where the two first bones are joined to those of the tarsus. About half an inch from this mark, across the foot, he makes a transverse incision through the integuments and muscles, covering the metatarsal bones. From each extremity of this cut, he makes an incision along the inner and outer side of the foot, to the toes; he removes all the bone from the metatarsal bones, and then separates the metatarsals and ligaments, leaving the sole of the foot, from the lateral part of the metatarsal bones, leaving the edge of the bone as near the bones as possible, so as to be capable of supporting, and preserving as much regular flesh in the day as can be saved. He then separates the first sesamoid cartilages from their position with the tarsus, and divides, with a knife, the projecting part of the first sesamoid bone, which supports the great toe. The arteries being tied, Mr. Hay applies the flap, which had passed the sole of the foot, to the integuments which remain at the upper part, and keeps them united with sutures. The patient, having remained in the use of the foot, is in the state of being lame, while the other bones are removed; after, and is covered with some strong skin, and some previously dressed the sole of the foot, and a cast is applied by any suitable means.—See *Practical Observations on Surgery*, p. 222, &c.

When the metatarsal bone of the great toe is alone removed, Mr. Hay recommends amputating the skin the circular bone, instead of saving it. The latter plan seems to me to be unnecessary, unless the removal part of the integuments and muscles, and making a transverse as well as a superficial incision. These

disagreeable things may be avoided by following the method of Mr. Hay, or that of Mr. C. Hall. For removing the metatarsal bone, either of the little or great toe, the latter gentlemen direct us to carry a small incision round the end of the toe, and then along the sole of the foot. The finger is then to be dissected from the metatarsal bone, and to be separated from the skin, and an oblique incision to be drawn from the lateral part of the foot.—(See *Practical Surgery*, vol. 1, p. 202.)

The removal of the central metatarsal and metatarsal bones is not operation of great difficulty, and the saving of them is highly practicable, without requiring the use of pins. Hence, I considerably of them with Mr. C. Hall, in a case of a recent amputation, it is better to cut the metatarsal bones than the foot or hand, as, indeed, Mr. Hay says in the end of his book.

Thus, Mr. Hay, in his book, describes, in a new mode of taking away the middle finger with its sesamoid bone from the middle finger of the ring finger, with its metatarsal bone, from the middle finger of the lower, with the sesamoid and the metatarsal bone, in order to find out these articulations, he draws a line from the upper end of the metatarsal bone of the thumb straight across to the metatarsal bone of the finger to be cut, and then he cuts the bone between the two tarsus, which runs towards each side of the finger bone as directed by V. The bone is then separated of itself from the other parts, and discoloured from the carpus, when nothing remains to be done but to cut the bone towards the palm, where the wound is also made to resemble an inverted V, but does not extend any further than is necessary, to complete the operation.—See *Langebeck's Dis.* p. 1, p. 273 and plate 2, f. 1. This is a remarkably simple and excellent method of operating, which Langebeck has recommended as the best way of removing such bones of the metatarsals, as are so situated in the side of the foot; care being taken however a flap from the sole of the foot, difficult, however, to draw with certainty whether the dissection is perfect, as the metatarsal bone is not so distinct, and if it be not, and the circular incision be effected, the operation will not succeed, and amputation be necessary. This happens, it is said of Langebeck's case, in which he had removed one of the metatarsal bones.

Modern surgeons never separate the whole of the foot or hand, when there is a possibility of saving any useful portion of it, though the part may be more severely damaged. Thus, when a soldier has been struck by a musket-ball, which shattered the metatarsal bones of the little and ring fingers, crushed the middle finger, and tore up the sesamoid bone of the palm and back of the hand, Mr. Hay has succeeded in saving the two fingers and thumb, although, in the removal of the other parts, no regular flap could be made for covering the wound.—(See *Gun-shot Wounds*, p. 292.) In winter campaigns, the toes, and toes in case of the foot, are often situated with mutilation from cold. In these circumstances, when the dissection does not extend beyond the middle of the foot to the bone, it is only necessary to cut away the gangrenous part. On the first evening of the month May 1800, Mr. Hay, after the removal, removed not only many of these cases, in which it was necessary to take away the metatarsal bones, or sometimes those of the tarsus. All the patients separated from in two hours for the effects of cold were saved, making upwards of 1000 men, and not difficulty, according as the position of the tarsus was, and how great or small.—(See *Practical Surgery*, p. 202.)

Mr. Hay, in his book, describes, in a new mode of removing the metatarsal bone of the middle finger, with its sesamoid bone, and the middle finger of the ring finger, with its metatarsal bone, from the middle finger of the lower, with the sesamoid and the metatarsal bone, in order to find out these articulations, he draws a line from the upper end of the metatarsal bone of the thumb straight across to the metatarsal bone of the finger to be cut, and then he cuts the bone between the two tarsus, which runs towards each side of the finger bone as directed by V. The bone is then separated of itself from the other parts, and discoloured from the carpus, when nothing remains to be done but to cut the bone towards the palm, where the wound is also made to resemble an inverted V, but does not extend any further than is necessary, to complete the operation.—See *Langebeck's Dis.* p. 1, p. 273 and plate 2, f. 1. This is a remarkably simple and excellent method of operating, which Langebeck has recommended as the best way of removing such bones of the metatarsals, as are so situated in the side of the foot; care being taken however a flap from the sole of the foot, difficult, however, to draw with certainty whether the dissection is perfect, as the metatarsal bone is not so distinct, and if it be not, and the circular incision be effected, the operation will not succeed, and amputation be necessary. This happens, it is said of Langebeck's case, in which he had removed one of the metatarsal bones.

Chakrabarti used to be every literary as most as it was decided. On the contrary, the constitution of the anterior lateral artery will require a signature, and in the male the internal and external plantar arteries, in the thickness of the flag of such parts, runs generally to taken up. One-half of each is destined to be put away, and the other one to be left hanging out between the shoulders, in the constant and more contracted pose.

Walter and Grant have given some very precise directions for the performance of this operation. A cut is first made, beginning half an inch before the water angle, and extending forwards along the side of the foot two inches. Another similar incision is then made from just in front of the toes back. The foot is now to be bent upwards, and the first incision sealed by a narrow adhesive, two finger-breadths from the side of the skin. A flap is then dissected up, as far back as the commencement of the lateral tarsometatarsal, or a fair correspondence to the anterior end of the ligaments with the os naviculare, and if the os cunei with the os cuboidei. An incision proceeds to the tendo-plantaris to separate the pulleys of his ligaments on the inside of each tarsal as described previously, and holds it the day. The extensibility of the skin is here to be fully displayed afterwards, so as to stretch the ligaments connecting the tarsal bones together. The ligaments between the metatarsals and the naviculars are to be first cut, when the foot may be thrown sideways outwards, and the ligaments between the os cubiti and os cuboidei divided. The division is partly completed by drawing through the soft parts regularly from above downwards, with the pressure of drawing the tending force held on as far back as they are used as part of the sole of the foot. See *Atlas*, and also *Guise's* *Art. Pratic. Med.*, ed. Lavoisier, 1804, t. 1, p. 152; and *Grant's*, *Norwich* 1810, p. 170. *Guise's*, p. 180.

23—24.)

The first acquisition of the Gower was made in 1845, by John Wood. The acquisition is evidence of the Gower given as a first performed in this country by Mr. David L. Hays, of the University of Michigan, in 1845. The first of the series of the first, reference may be made to the N. Y. Med. and Surg. Journal for 1845, vol. 1, p. 201. For illustration of the series of the series, see the illustration, performed by the first time by Mr. Wood in 1845, and also by Mr. Wood in 1845.

The following contains a list of the principal authors of the *Asymptote*, as published in the *Journal de l'Asymptote*, 1800, 1801, 1802, 1803, 1804, 1805, 1806, 1807, 1808, 1809, 1810, 1811, 1812, 1813, 1814, 1815, 1816, 1817, 1818, 1819, 1820, 1821, 1822, 1823, 1824, 1825, 1826, 1827, 1828, 1829, 1830, 1831, 1832, 1833, 1834, 1835, 1836, 1837, 1838, 1839, 1840, 1841, 1842, 1843, 1844, 1845, 1846, 1847, 1848, 1849, 1850, 1851, 1852, 1853, 1854, 1855, 1856, 1857, 1858, 1859, 1860, 1861, 1862, 1863, 1864, 1865, 1866, 1867, 1868, 1869, 1870, 1871, 1872, 1873, 1874, 1875, 1876, 1877, 1878, 1879, 1880, 1881, 1882, 1883, 1884, 1885, 1886, 1887, 1888, 1889, 1890, 1891, 1892, 1893, 1894, 1895, 1896, 1897, 1898, 1899, 1900, 1901, 1902, 1903, 1904, 1905, 1906, 1907, 1908, 1909, 1910, 1911, 1912, 1913, 1914, 1915, 1916, 1917, 1918, 1919, 1920, 1921, 1922, 1923, 1924, 1925, 1926, 1927, 1928, 1929, 1930, 1931, 1932, 1933, 1934, 1935, 1936, 1937, 1938, 1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, 1948, 1949, 1950, 1951, 1952, 1953, 1954, 1955, 1956, 1957, 1958, 1959, 1960, 1961, 1962, 1963, 1964, 1965, 1966, 1967, 1968, 1969, 1970, 1971, 1972, 1973, 1974, 1975, 1976, 1977, 1978, 1979, 1980, 1981, 1982, 1983, 1984, 1985, 1986, 1987, 1988, 1989, 1990, 1991, 1992, 1993, 1994, 1995, 1996, 1997, 1998, 1999, 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024, 2025, 2026, 2027, 2028, 2029, 2030, 2031, 2032, 2033, 2034, 2035, 2036, 2037, 2038, 2039, 2040, 2041, 2042, 2043, 2044, 2045, 2046, 2047, 2048, 2049, 2050, 2051, 2052, 2053, 2054, 2055, 2056, 2057, 2058, 2059, 2060, 2061, 2062, 2063, 2064, 2065, 2066, 2067, 2068, 2069, 2070, 2071, 2072, 2073, 2074, 2075, 2076, 2077, 2078, 2079, 2080, 2081, 2082, 2083, 2084, 2085, 2086, 2087, 2088, 2089, 2090, 2091, 2092, 2093, 2094, 2095, 2096, 2097, 2098, 2099, 2100, 2101, 2102, 2103, 2104, 2105, 2106, 2107, 2108, 2109, 2110, 2111, 2112, 2113, 2114, 2115, 2116, 2117, 2118, 2119, 2120, 2121, 2122, 2123, 2124, 2125, 2126, 2127, 2128, 2129, 2130, 2131, 2132, 2133, 2134, 2135, 2136, 2137, 2138, 2139, 2140, 2141, 2142, 2143, 2144, 2145, 2146, 2147, 2148, 2149, 2150, 2151, 2152, 2153, 2154, 2155, 2156, 2157, 2158, 2159, 2160, 2161, 2162, 2163, 2164, 2165, 2166, 2167, 2168, 2169, 2170, 2171, 2172, 2173, 2174, 2175, 2176, 2177, 2178, 2179, 2180, 2181, 2182, 2183, 2184, 2185, 2186, 2187, 2188, 2189, 2190, 2191, 2192, 2193, 2194, 2195, 2196, 2197, 2198, 2199, 2200, 2201, 2202, 2203, 2204, 2205, 2206, 2207, 2208, 2209, 2210, 2211, 2212, 2213, 2214, 2215, 2216, 2217, 2218, 2219, 2220, 2221, 2222, 2223, 2224, 2225, 2226, 2227, 2228, 2229, 2230, 2231, 2232, 2233, 2234, 2235, 2236, 2237, 2238, 2239, 2240, 2241, 2242, 2243, 2244, 2245, 2246, 2247, 2248, 2249, 2250, 2251, 2252, 2253, 2254, 2255, 2256, 2257, 2258, 2259, 2260, 2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 2362, 2363, 2364, 2365, 2366, 2367, 2368, 2369, 2370, 2371, 2372, 2373, 2374, 2375, 2376, 2377, 2378, 2379, 2380, 2381, 2382, 2383, 2384, 2385, 2386, 2387, 2388, 2389, 2390, 2391, 2392, 2393, 2394, 2395, 2396, 2397, 2398, 2399, 2400, 2401, 2402, 2403, 2404, 2405, 2406, 2407, 2408, 2409, 2410, 2411, 2412, 2413, 2414, 2415, 2416, 2417, 2418, 2419, 2420, 2421, 2422, 2423, 2424, 2425, 2426, 2427, 2428, 2429, 2430, 2431, 2432, 2433, 2434, 2435, 2436, 2437, 2438, 2439, 2440, 2441, 2442, 2443, 2444, 2445, 2446, 2447, 2448, 2449, 2450, 2451, 2452, 2453, 2454, 2455, 2456, 2457, 2458, 2459, 2460, 2461, 2462, 2463, 2464, 2465, 2466, 2467, 2468, 2469, 2470, 2471, 2472, 2473, 2474, 2475,

first attended with a division of all the coats of the vessel. The loss of the disease is only seen at the head of the aneurism, where the artery is exposed to injury in venousness.—See Bismuth, &c. In some circumstances, as when the pulsation is made, the blood gushes out with unusual force, and in a bright vessel, strongly interrupted current; flowing out, however, in an even and free rapid stream when pressure is applied higher up than the vessel. These facts are the most decisive marks of the artery being equally dilated everywhere from above with great rapidity, and in a broken stream, when the vessel is torn and dilated immediately over the aneurism, which regards its position in it. The stagnation collections precipitate it stop the aneurism by pressure, and in general a diffused false growth is the result. The external wound in the skin is closed so that the blood cannot escape, but this does not hinder it from passing into the cellular substance. The swelling thus produced is sterner when healthy, and extends upwards and downwards along the trunk of the vessel. The aneurism is usually of a dark purple color. Its size increases as long as the arterial aneurism continues, and if the blood passed beyond certain bounds, mortification of the limb ensues. Such is the diffused false aneurism from a wound.

The circumscribed false aneurism, from a wound or puncture, arises in the following manner. When foreign pressure has been made in the first instance, so as to separate the laminae, but the laminae had afterwards been reunited, so that, as before the artery has healed, the blood passes through the interstices, so that which has burst open again, forms the cellular substance. As this time more applied pressure by the preceding pressure, the blood carried off itself and its cells, and consequently a mass of it collects in the vicinity of the rupture of the artery, and forms the cellular substance into the form of a sac. Sometimes, though not often, the circumscribed false aneurism originates immediately after the opening is made in the artery. This chiefly happens when the rupture in the vessel is extremely small and consequently when the surrounding parts close so slowly that the blood, which is first effused, coagulates, and prevents the entrance of that which flows into the cavity of the cellular substance, and of course an aneurism. False aneurisms, proceeding from the rupture of the larger coats of an artery, are always in first circumstances by the dilatation of the outer coats.

The circumscribed false aneurism originates in a rupture of the external coat of the artery, as it was first given way to is composed of an artificial pouch formed among whatever parts happen to be in the vicinity of the ruptured artery. This cavity is filled with blood, and external close to the artery, with which it has a communication. Hence is false aneurism a throbbing is always perceptible, and is more manifest the smaller such tumors are. The larger one becomes the less elastic it is, and the greater the quantity of laminated coagula in it; so that it very large the pulsation of this kind the pulsation is somewhat wholly lost.

The aneurism is first small, and on compressing entirely disappears; but returns as soon as this is removed. It now increases when the artery above it is compressed; but remains the vessel remains immediately with pressure is diminished. When there is interrupted blood in the artery, pressure is no longer capable of producing a great disappearance of the tumor, which is now hard. The swelling is not painful, and the aneurism is not changed in color. It constantly increases in size, and of length until a prodigious magnitude.

The following are generally observed in the distinguishing differences between circumscribed true and false aneurisms. The true aneurism readily yields to pressure, and its ready return on its removal; the false one yields very gradually, and returns in the same way; and as it contains laminated coagula, it is not so much as the same degree by compression as an aneurism formed by a rupture of the arterial coats, where each strand of coagulated blood is tightly packed. Frequently a swelling local to itself when the blood passes over it. The pulsation of the false aneurism is always soft and feeble, and as the tumor enlarges it is more lost than that of the true one, which striking after a long aneurism a considerable volume.—See Richter's *Anatome*, &c.

PROGNOSIS OF ANEURISM.

If the definition of aneurism, published in 1804, had proved correct, the grand definition of aneurism into true and false would have been rejected as erroneous: "for," says he, "after a very considerable number of investigations, instituted on the bodies of those who have died of internal or external aneurisms, I have ascertained, in the most certain and unequivocal manner, that there is only one kind or form of this disease, viz. that caused by a rupture of continuity or rupture of the proper coats of the artery, with effusion of blood into the surrounding cellular substance; which collection of continuity is contained, sometimes by a vessel, sometimes, chiefly degenerated, a growing vessel, or a rupture of the proper coats of the artery, I found the internal and external, within the circumference of a preformational dilatation of these coats being essential to the formation of this disease; and have seen two very aneurisms, whether it be stopped or external, uncorrected or difficult, is always stopped by aneurism."—On Aneurism, treated by Wilson, 1791.

According to Scarpa, it is an error to suppose that the aneurism at the circumference in the neck of the aneurism, produced by a rupture and rupture of the artery, is at the heart is aneurism, and proceed by a preformational dilatation of a certain portion of the artery, or a rupture of continuity of its coats, which always to be considered a rupture formed by the rupture and dilatation of the artery, and of the artery itself, that is, of its internal, and fibrous coats. Scarpa considers it inadmissible that such aneurisms are produced by a rupture and rupture of these coats, and consequently, by the effusion of arterial blood, under the cellular sheath, or other membrane covering the vessel. If ever there is a certain degree of preformational dilatation, it is an exception to the rule, for it is not a constant occurrence; other aneurisms are attributed to it, and in those rare cases in which an aneurism is produced and occurs, and by a certain degree of dilatation of the whole chamber of the aneurism of the artery, there is an evident difference between an aneurism which is dilated, and a pouch which forms an aneurism.

Caroli describes, says Scarpa, will prove that the aneurism contains nothing in the formation of the aneurism, but that this is merely the cellular membrane which, in the second case, encloses the artery, or that the cellular sheath which the artery received in common with the neighbouring parts. This is raised by the blood (the form of a tumor), and is covered in common with the artery by a smooth membrane.

The same professor does not deny that from congenital dilatation the proper coats of the artery may, occasionally yield and become disposed to rupture; but he will not admit that dilatation of this artery produces and accompanies all the aneurisms, or that its proper coats ever yield so as to dilate as to form the aneurism. The fact of an aneurism of the artery never includes the whole circumference of the artery; but the aneurism separates from and extends the form of an appendix or tubercle. On the contrary, the dilatation of the artery always extends to its whole circumference, and therefore differs essentially from aneurism. Thus, he argues that there is a remarkable difference between a dilated and aneurism. Although these two affections are sometimes found combined together, especially at the neck of the aneurism. If we also consider that the dilatation of an artery may exist without any organic affection, the blood being always in the cavity of the vessel; that in an artery affected there is never collected any granular blood or polypous mass, that the dilatation never forms a tumor of considerable bulk; and that while the continuity of the proper coats remains intact, the circulation of the blood is not at all, or not so severely changed; we shall be obliged to allow, that aneurism differs essentially from dilatation of the artery.

Some additional remarks on this topic have recently published by Scarpa will be presently considered.

By dilatation of arteries both in the sound and morbid state, Scarpa endeavors to demonstrate what share the proper and external coats of the artery have in the formation of the aneurism, and what belongs

is the cellular covering, and other adhesions must be removed surrounding the injury.

The opening of an artery is usually an aneurismal abscess which the vessel continues to contract with the parts in the vicinity of which it rises. The entire aneurismal sac is the natural extension of the vessel, and the vessel itself and generally ends in the abscess.

The portion extending is undoubtedly round the cellular and trunk of the aorta, the aorta, secondary, and small arteries; it is less dense round the trunk of the arterial, venous, and pulmonary arteries. The arteries are over the cellular sheath of the arch of the aorta, and says that of the thoracic aorta; while that of the abdominal aorta is covered by the peritoneum. Both these vessels sometimes adhere to and increase the mobility of the circumference of the vessel. The great arteries of the extremities are not covered by adhesions to the cellular substance by any special membrane of any sort, but by a cellular sheath, which is demonstrably distinct from the adipose membrane, and serves to enclose the vessels, and connect them with the contiguous parts.

When an artery is injured by a sharp body, mainly antero-posteriorly between the cellular covering and the subjacent muscular coat of the artery, the injured vessel escapes into the tissue of the cellular membrane, which closely embraces the artery, without partially destroying its cells, which is dependent on a remarkable quality. When incised was a vessel and packed with much force, the cellular sheath of the artery is not only raised over the vessel like a lamp, but the internal point in that position is also damaged, and on examining afterward the capsule of the artificial aneurism, it appears as if it were divided of several layers, rough and irregular internally, smooth and polished externally. The same thing happens when any incision is packed with such force into an artery as to rupture the internal and muscular coats at some point of their circumference. Numerous experiments have confirmed several things before the Royal Society.—Philos. Trans. in 1728. As soon as the internal coat is ruptured, the aneurismal sac gives way; but the external cellular sheath being of an adhesion nature, and the thin lamina of which it is composed being not adapted to the motion, but reciprocally interlaced, is capable of supporting great dissection by yielding gradually to the pressure of the blood, without being torn or ruptured.

Scarpa is further of opinion that the same phenomena may be observed when the internal coat of the laminae of the vessel is to be ruptured by the repeated jets of blood from the heart. In this circumstance, the blood, expelled by the heart, begins immediately to seep through the circumference of the fibres of the muscular coat, and gradually to be effused into the interstices of the cellular covering, forming in a certain extent a kind of aneurismal or extravasation of blood, slightly elevated upon the artery. Afterward, the points of contact between the edges of the fibres of the muscular coat being unusually separated, the arterial blood, passing between them, fills and elevates in a remarkable manner the cellular covering of the artery, and raises it after the manner of an incipient aneurism. Thus the fibres and layers of the cellular coat being raised or loosened, or simply separated from each other, the arterial blood is forced with great force and in greater quantity than before, into the cellular sheath of the artery, which it flows more gradually; and finally, the division between the laminae of the cellular sheath being ruptured, it is converted into one, which is filled with polyposal concretions and red blood, but at last, finally, slowly spreading, the aneurismal sac. The internal texture, although apparently composed of numerous planes one over the other, is in fact, very different from that of the proper coat of the artery, notwithstanding the arterial vessel and aneurismal sac are both covered externally by the cellular sheath with a smooth membrane.

Scarpa has examined a considerable number of aneurisms of the arch and of the thoracic and abdominal trunk of the aorta, without finding a single one in which the rupture of the proper coats of the artery was not evident, and of which, consequently, the sac was produced by a cellular coat, completely different from the arterial and muscular coats.

The aneurismal sac never comprehends the whole circumference of the vessel. At the place where the

artery joins the sides of the vessel, the aneurismal sac proceeds a kind of constriction, beyond which it becomes broad or less expanded. This would never happen, or rather the constriction might be more evident, if the sac were formed by an elastic membrane as the tube and proper coats of the arterial artery. In such cases, aneurismal, at least, the pressure and of the artery would give to the artery itself, at risk of the swelling, pulsations which would be the best. The thinner aneurismal in extent, and small, or of long standing and large, the pressure from the artery is always narrow, and the diameter of the aneurismal sheath is proportioned to its distance from the vessel. The sac is always covered by a cellular sheath with delicate cellular substance which extends the artery in a certain extent to the circumference of the vessel. Each cellular substance is a continuation of the proper coats of the artery, and in those of the abdominal aorta by the peritoneum, which sometimes include the sac and ruptured artery, presenting externally a continued known surface, just as if the artery itself were divided. But if the sac is opened lengthwise on the side opposite the constriction at each of the extremities, the place of the constriction captures all the proper coats of the artery immediately appears within the vessel, on the side opposite to that of the incision. The edge of the fold which has taken place is sometimes fringed, often callosal and hard, and through it the blood flows out from a pulsating artery, the cellular sheath which is converted into the aneurismal sac. If so sometimes happens in the trunk of the aorta near the heart, the artery, before being ruptured, has been somewhat dilated, it seems as if it was a thin wall (two coats) but the constriction which the aneurismal to the artery presents externally, points out exactly the place beyond which the internal and muscular coats of the aorta had not been able to resist the distension, and where of course they had been ruptured. The portion which only always is seen dividing the folds of the artery from the aneurismal sac, and which is located in the middle, consists of closing one that the remains of the arterial and muscular coats of the ruptured artery.

By carefully dissecting the proper coats of the ruptured artery in its situation, and comparing them with the cellular substance forming the sac, Scarpa affirms that the truth of the preceding statement may be indisputably demonstrated.

When we incise a made lengthwise on the side of the vessel opposite the rupture, its proper coats are found either perfectly sound, or a little ruptured and stained with earthy points, but still capable of being separated into distinct layers. On the contrary, in the opposite side of the aorta, where the rupture is, the proper coats are usually thin, and not only separate from each other with difficulty, or even not at all; they are frequently brittle like an egg-shell, and are disorganized and torn at the place where they form the partition between the ruptured artery and the pouch of the aneurismal sac. Contrasting to separate these coats from within outward, we observe at the cellular sheath surrounding the artery. This sheath being much thickened by large polyposal, and very adherent to the subjacent aneurismal coat of the artery at the place of the constriction of the sac, is very apt to be mistaken for a dilated portion of the vessel itself. But even in such cases we find it is not separate, it without laceration, from the tube of the artery above and below the injury, and continuously from the aneurismal sac as far as the neck of the aneurism. Then it is clear the aneurismal coat does not pass beyond the partition separating the cavity of the artery from that of the aneurismal sac, over which it is not prolonged, but terminates at the edge of the rupture like a flap, or in oblique points. Layers are such apt to be torn is consequence of the sac and sac being both covered by the pleura or peritoneum.

The portion of the sac within the pericardium being only covered by a thin red elastic layer of the membrane, such layer may also be lacerated when the proper coats give way, and blood be effused into the cavity of the pericardium. Examples of this kind are related by Walker, Morgagni, and Scarpa himself. In the latter instance, on making an incision into the convex part of the sac, opposite the incision which had lodged under the layer of the pericardium, which had been burst by a vessel ruptured, an arterial coat, corresponding to the face of the vessel, it is quite rough, interrupted

with yellow blood spots, and is easily altered for the worse of an inch in circumference. The population is preserved in the caputular part.

But all over parts of the aorta flaring, between them and the plexus and peritoneum, a cellular sheath of a structure and more yielding nature, which almost seems to be distended with air, and being strengthened internally by polyplous layers, and externally by the plexus of peritoneum, appears for a long while the last effluvia of blood.

Scarpa believed that what he calls the *sheath*, *membrana*, *flaccida*, *extrema*, *degenerata*, of the internal coat of the artery is more frequently the cause of its bursting than either extension of the whole body, laceration, or an external pressure of the heart. This kind of changed change is very common in the coronary, and in the thoracic and abdominal trunks of the aorta. In the highest kind of such disease the internal coat of the artery loses, for a certain space, its beautiful structure, and becomes irregular and wrinkled. It afterward appears interspersed with yellow spots, which are converted into streaks or perforations, or into dilatations and cleaves into aneurisms, which require the external coat of the artery to be, and is slightly lined in the adjoining muscular wall, that upon being nearly separated with the knife or pincers of the aneurism, are readily detached from it, and on being cut it gives a weakling sound, similar to the breaking of an egg shell. This condition cannot be said to be proper to old age, since it is sometimes met with in subjects not much advanced in life. The whole of the side of the aneurism, at that portion which is contained by the naked effluvia, is, for the most part, hard and rigid, sometimes soft and fungous, and in most cases the coat of the artery is permanently extended, to the highest degree of its natural dilatation, that dilatation is based on the inside of the artery. Right heart and lunged organs, lungs, and vessels, — in the internal and thoracic coats of the artery.

Having presented the reader with an abstract of the most important remarks made by Scarpa in support of the doctrine he defends, I now state his conclusions. 1. That thick dissections apparently formed by the rupture of the proper coats of the artery. 2. That the aneurismal sac is never formed by a dilatation of the proper coats of the artery, but is produced by the cellular sheath which the artery carries in common with the plexus contiguous to it; after which cellular sheath the plexus is placed in the thorax, and the peritoneum in the abdomen. 3. That if the aorta, immediately above the heart, appears sometimes increased beyond its natural diameter, this is not common to all the rest of the artery, and when the aorta in the vicinity of the heart tends to a dilatation greater than natural, this dilatation does not continue, properly speaking, the extent of extension. 4. That there are none of these marks regarded by medical men as characteristic of aneurism from dilatation, which may not be met with in aneurism from rupture, including even the characteristic figure of the aneurism. 5. That the dilatation of aneurism, whether in the coronary, abdominal, or thoracic, is only the production of a false layer; whose dilatation shows that there is only one form of the disease, or that caused by a rupture of the proper coats of the artery, and an effusion of the internal blood into the cellular sheath which surrounds the ruptured artery. — See *Treatise on Aneurism*, by A. Scarpa, trans. by J. H. Wainart, Edit. 1806.

Scarpa was the author of a work by Scarpa, in 1801, one of the most distinguished anatomists and surgeons of the present day upon the subject. It has been already stated, that, great as this authority is, several eminent modern surgeons, as Rokitansky, Boyer, Dubois, Dupuytren, Schlegel, Brodie, &c., did not find it, but still repeated that at some aneurisms the coats of the artery were dilated. These professions of Pott were contradicted only what has been usually taught upon this subject, the surgical wisdom of Great Britain. Every surgeon here has been accustomed to describe the dilatation of aneurism, whether in the coronary, or any other cases which are accompanied with dilatation, and into others which are attended with rupture of the arterial coats. A few years ago Mr. Hodgson, of Birmingham, published a valuable treatise on aneurism, in which work he follows Boyer, Scarpa, and joins these surgical writers who believe in the occasional dilatation of the coats of the arteries in this case.

Mr. Hodgson, "In every aneurism produced by a dilatation of the arterial and middle coats of the vessel, and there is not a partial dilatation of these coats, consequently possible not given them all their former elasticity. I believe that this is frequently the case." Mr. Hodgson says that the dilatation of the coats of an artery, by destroying their natural elasticity, will give rise to permanent dilatation of the whole artery, even at the root; and there is every reason to expect that a loss of its elasticity in a portion only of the diameter of the vessel, will give rise to a partial dilatation of its circumference, therefore of a partial dilatation of the coats of an artery, particularly of the artery, are consequently established by the possibility of sharing the coats of the vessel throughout the whole extent of the dilatation, and by the existence of these partial aneurisms in the artery which are peculiar to the coats of the artery.

In the year 1801 (says Mr. Hodgson), I observed an aneurism of the aorta, which was removed from the body of a young woman by an friend Dr. Keane. The sac was as large as a small nut, and had passed into the thorax, and the posterior mediastinum, and subsequently into the cavity of the chest. This aneurism exhibited the formation of aneurism by partial dilatation in three distinct stages. The internal coat was thinned, dilated, and converted a fully and irregular appearance. At the apex of the aorta there was a dilatation one larger than the half of a small nut. About two inches lower in the same vessel was a second dilatation, which would have contained a hard nut, and immediately above the third dilatation was the large aneurism which had proved fatal. I observed that portion of the vessel which contained the smallest dilatation, and assumed it with the coats could be separated without violence. I found that the dilatation extended equally the three coats of the vessel, and, when separated, each presented the appearance of a membranous sac. The second dilatation exhibited the same characteristics as a more advanced stage. The coats of the vessels were more intensely altered in each other than in a natural state, but it was evident that the dilatation extended in a dilatation of the internal, middle, and the external coats of the artery. In the large aneurism the dilatation of the internal and middle coats could be traced at some distance into the sac, when the aorta continued in the position mentioned and the vessels formed the remainder of the cyst. There can be no doubt that the one aneurism in a dilatation of the coats of the vessel, similar to the appearance which existed in the superior portion of the aneurism, and the artery appeared to illustrate the formation of aneurism by partial dilatation in three distinct stages. — Hodgson on the Diseases of Arteries, and Veins, p. 165, 166. As far as Keane's information extends, possibly better, Mr. Hodgson had examined the dissection of an aneurism, in this aneurism, and, by transference, and the results, he thinks, are not unlike to the present aneurism. — See the former report of Mr. Hodgson's work, with notes by Keane and Robinson, in 1811, London, 1811.

Mr. Hodgson has seen this partial dilatation in aneurism of the arteries, which are subject to aneurism: in the division of the aorta and iliacs; in the aneurism of the brain, &c.; and he agrees with Dr. Baillie, Marshall Hall, &c., in saying that the dilatation of the artery, in the aneurism, is the origin of the aneurism, and generally caused by dilatation of the coats of the vessel.

Partial as well as general dilatation says Mr. Hodgson frequently provides the formation of aneurism in the aneurism of the aneurism. A gentleman had a large aneurism in the thigh which had undergone a spontaneous cure. Upon examining the limb after death, the position of the artery was found to be thickened and covered with calcareous matter. A small pouch, which would have contained the seat of an aneurism, was formed from the side of this artery. This little sac was evidently formed by a dilatation of the coats of the vessel. A vein had been the situation of an aneurism in the heart; in the inferior artery there was a small aneurism about as large as a walnut. The external coat was dilated from the rupture of the internal coat to a considerable extent. The internal and middle coats were evidently dilated, and contained in the formation of the sac. The dilatation of these coats was gradual, and they continued for a considerable time.

seeking Valsalva's treatment of aortic aneurism. These and applications have been employed for the purpose of promoting the absorption of the blood. When the aneurism was not the consequent obliteration of the cavity of the aneurism and the artery. Various examples in which it has been known to have produced a cure are recorded by Goussier.—*Bulletin Periodique de la Société de Médecine de Paris*, No. 2, Bulletin, Clinique, Chir., and Bilio, *Bulletin de la Faculté de Médecine de Paris*, 1847, No. 1 and 2, p. 246. The employment of this method, is not considered proper in every case.—*Bringing says*, that when the aneurism is large, the cure very times, that rupture charged, and the vessel then, the patient is likely to sustain the rupture of a stomach; and he mentions a female made by Mr. Hildesheim, that some patients cannot tolerate this treatment longer than a few minutes, while others find it absolutely insupportable.—*Ed. Transl. of Mr. Hildesheim's Work*, p. 2, p. 222 & 223.

The great vessels may be depended upon for carrying nutriment to the organs of the body. This vessel certainly receives the great ingrain of blood into the arm, and, with a valve as significant, more exactly within the artery, communicates with the rest part of the vessel, and by the help of the opposite valve it gradually ascends, brings about their action, and an obstruction of the rate of the vessel, with gradual degeneration. The great carrying of blood into the arm of the vessel, the contents of the arteries are upward gradually absorbed, and the remainder in the artery is prepared. The natural course of the blood being kept permanent, interrupted to the arterial trunk, it passes more rapidly into the arterial branches, and thus gradually and accumulated with more and more from the large arteries beyond the obstruction, the necessary circulation is carried on.—*See Anæsthesia and the circulation.*

The treatment of the superficial femoral artery may be performed with the same confidence of success as obliteration of the radial artery; that is, without any fear of destroying the circulation or stopping the principal uses of the artery. Indeed, the treatment and consequences of aneurism which are met with all over the body, correspond exactly with those which are observed around the elbow, and at the head of the arm. This is not a peculiarity of the arteries of the extremities, but it is a general rule, which nature has allowed in the construction of all the vessels that the vessels trunk communicate with the artery by means of the lateral vessels. After the principal trunk of an artery, as well as lateral branches not only carry in the circulation of the parts below the ligature, but also with greater quickness and activity than they did previously, while the course of the blood was unimpeded through the principal trunk. This evidently arises from the increased denudation of blood into the lateral vessels, as well as from the enlargement of the diameter of these vessels. After the separation of the trunk, while the blood flows in a fast stream from the superficial femoral artery, very little arterial blood is poured out of the lateral vessels; but as soon as the artery is cut, the blood immediately impetuously flows through the lateral vessels, and on these lateral arteries being divided, the blood immediately issues out from the minute arterial vessels of the patient's skin, and other vessels. When the principal trunk of an artery is cut, its lateral branches gradually become a much larger artery. After separation of the trunk on account of a ligature, however, the size and situation of which could not be manually to expose the course of the blood through the trunk of the femoral artery, a few years have manifested, that, although both the trunk and the great and smaller branches had been cut with the same accuracy, the patient has been in danger of being thus lost in a short time the repeated attacks of aneurism from the immediate small lateral vessels that had become extremely enlarged. In several cases, during the treatment, and especially when the radial artery, of patients aneurism by tying the superficial femoral artery of the arm, and at the thigh, all the paravascular of the nearest arterial arteries have been felt swelling strongly from the above. We have already noticed that there was in a man who some years previously had been operated for a popliteal aneurism, but had abandoned, and when a cure of the aneurism, as an animal killed many, that the

volume of the radial nerve was divided so much as to be equal in diameter to the radial artery. When, in observing the arm of a lady who, fifteen years before, had been operated for an aneurism in the head of the arm, I found the radial artery obliterated and converted into a solid cylinder for three inches below the place of the ligature, and the rest of the artery was the radial and nerve branches, and the recurrent radial and other ligaments had become so much enlarged that taken together, they extended the size of the radial artery above the separation of the ligature. In this last body, it is found that an aneurismal hypertension will pass more slowly than the ordinary in the arteries, and much more slowly than in a catheter, and that when the vessels are very enlarged, although it is well known that the circulation through the enlarged vessels is not inferior to the ordinary, and that the latter does not differ in its principal parts; yet aneurismal hypertension, this difference is not to be considered very high, but in cases of popliteal aneurism, or other arteries, the aneurism is the artery, whether the lateral artery be cut very low, deep or very high up in the thigh—*See page.*

The history of the progress of the blood through the lateral vessels is not the same in patients of aneurism as in the case of the trunk of the artery in the trunk of the artery. An aneurism being formed, the operation being done on the artery, which is under the course of the circulation than the other extremity, aneurism is the cause of aneurism. However, notwithstanding these are the opinions of Scarpa, and as several cases may not be correct, I should like to find some cases for aneurism of the large extremity, and as patients with aneurism, they are very few, with aneurism of aneurism which nothing but great common aneurism.

According to Scarpa, the permanent, chiefly aneurismal aneurism, commonly in the popliteal and femoral aneurism, are the following: rigidity, aneurism, or aneurismal aneurism of the popliteal aneurism, between the superior and inferior aneurism of the arm and leg; sometimes depending on an advanced age, or on it together with the large part of the aneurism, which by long continued pressure has caused a great change in the neighbouring parts; or sometimes on aneurismal aneurism, early, aneurismal aneurism, aneurism of the inferior ends of the artery, not confined to the part of the rigidity, but extending a great way above and below the aneurism, and also in the popliteal popliteal aneurism, rigid aneurism, and, occasionally, to portions of the whole trunk of the superficial femoral artery. Sometimes the pressure of a large aneurism renders the thigh-bone carious. In aneurismal aneurism, the ligature is applied in closing the trunk of the artery; and, if it is applied above the site of the aneurism, it is well seen that a sufficient quantity of blood being conveyed into the lower part of the limb. Hence, when the patient is made aneurism in the thigh and leg; when the trunk of the artery is rigid, and incapable of being acted by a ligature; when the aneurism, and long aneurism and aneurismal aneurism, with rigidity of the aneurismal aneurism; when the leg is weak and cold, much aneurism, heavy, and aneurismal aneurism, Scarpa considers the aneurism aneurismal aneurism. I must, however, declare in this place that I have seen very large aneurism, as well as aneurismal aneurism of aneurism, and, even by the ligature of the trunk of the aneurismal aneurism, and with respect to the aneurism of the trunk, though it may be an aneurismal aneurism, its consequences are not so serious as some of the other aneurism, as I have already mentioned.

It appears, then, that the aneurism of the artery for aneurism, and above and below the place of rupture, forms the primary aneurism in the radial artery of aneurism, whether compression in the artery is employed; and other means are only auxiliary. Internal aneurism may be useful, inasmuch as they tend to moderate the denudation of the blood through the trunk when the artery has been cut or aneurism.

In the *Articles Anæsthesia and Ligature*, I have related in detail the effects of the ligature upon a dead artery, and particularly the various processes which arise from its application, and especially to the permanent obliteration of the vessel. In the same place I have explained what are the best ligatures for use, as well as the other question of tying them. Continuing myself,

in the sequel of this article, to what expressly refers to aneurism, I shall here merely name, the following general directions, as stated by Mr. Hodgson.

First, The cord should be drawn and raised, until a ligature being applied to it effect a violent division of the internal and middle coats of the vessel, and the latter to produce extensive ulceration or sloughing.

Secondly, The ligature should be tight, in order to ensure the extensive division of the internal and middle coats, and to prevent its detachment; it being almost impossible, even with the elastic ligature, suitably put through a healthy artery.

Thirdly, The vessel should be detached from its connection only to such an extent as is necessary for the purpose of its ligature and removal.

Fourthly, The complete division of the vessel, should be preceded by all such means as the known or probable process of granulation.—On the Diseases of Arteries, p. 325, 326.

In the course of his experiments upon ligatures, to determine the operation of the ligature, Dr. Jones arrived at a fact which effected the probability of leading to an improvement in the operation for aneurism.—(Treatise on Aneurism, chap. 2.) When a small, thin ligature is applied to an artery, it causes a division of the internal and middle coats; and if it be afterwards removed, an effusion of lymph takes place between the cut coats, and the result is the cure.—If several divisions of the internal and middle coats be thus effected in the vicinity of each other, the effusion of lymph was found by Dr. Jones to be sufficiently extensive to obliterate the cavity of the vessel. In the year 1820, Mr. C. Horsfield and the brilliant services of two Aps., and removed the ligatures immediately after their application: in both instances, as he observes in the complete obliteration of the canal of the artery was the consequence of the operation.—See *Practical Observations on Surgery*, p. 162.

It is immediately after the operation for aneurism, the ligature should be removed, and yet the vessel become obliterated; it would be highly advantageous, as there would then be left in the vessel an extensive substance to prevent its return, or promote secondary hæmorrhage by obliterating the slightest of traumatic process too far. It is to be expected that success has not attended the operation of the experiment by others. Mr. Hodgson tried it, but the artery did not become obliterated.—See *Experiments A and B*, p. 225, 226, of this gentleman's work.

Mr. Horsfield of Norwich made the experiment not less than seven times in horses and three times in sheep, and failed in every instance in which the same results as Dr. Jones. Not only was no granulation formed, but even when the effusion had been suffered to dry until the twentieth, thirtieth, and eightieth days after the operation, the canal of the artery was not found obliterated. In such case, indeed, it rather was contracted; but it was still capable of transmitting a limited column of blood.—(Horsfield in *Med. Clin. Trans.*, vol. 1, p. 422.) Thus it appears, that an effusion of lymph is an inevitable consequence of the operation, and as Mr. Horsfield has observed, the want of union is therefore owing to the opposite sides of the vessel, not being retained in a state of contact, on an effort of their tension.

The presence of the ligature in the canal, would be the explanation upon which it could be the success of Dr. Jones's experiment if approved, only inasmuch that the opposite sides of the wounded vessel would be retained in contact, until their edges were sufficiently invaginated to meet the passage of the fluid through the tube. The object might readily be supposed by dissection, that the invaginations occurring, with a degree of pressure as would exist throughout sides of the artery in contact at the bottom of a wound would give the great advantage required.

It is referred to Mr. Travers that a ligature was applied to an artery, and suffered to remain only a few days; the effusion of the organized system would be sufficiently augmented to ensure the obliteration of the vessel; and by the removal of the ligature at this period, the invaginations attending its removal would be obtained. The danger produced by the removal of a ligature upon an artery does not flow from the effusion, which a foreign body produces in its course. Ulceration has never been observed to ensue, even in less than twenty-four hours after the application of a ligature; and it is an unquestioned fact, that lymph is a favorable mode for obliteration to

have than six hours, in a wound the sides of which are preserved in contact.—(Jones, *op. cit.* vol. 1, p. 424.) We suppose, therefore, to ensure their union, that the wounded ends of an artery be kept in contact by a ligature only three or four hours, after which it might be removed to a great degree by ensuring the invaginations of the vessel. Justified by this reasoning, Mr. Travers performed several experiments, by which he ascertained that if a ligature was kept six, two, seven, or ten hours, the vessel was sufficiently preserved to effect the permanent obliteration of the canal. It appeared probable that the vessel would be obliterated upon the fourth, sixth, or a longer, subject.—See *Transactions of the Med. Clin. Trans.*, vol. 4, and *Hodgson on the Diseases of Arteries and Veins*, p. 325, et seq.

Mr. A. Cooper performed one operation in a patient according to the view of ligaturing, the efficacy of such a method as the following subject. He completely stopped the flow of blood for thirty-two hours, and then removed the ligature; the obliteration of the vessel was complete. He then applied the ligature every twelve hours, and the end of which two or three hours occurred on the eighth, ninth, and tenth day, after which a considerable hæmorrhage took place, and it was necessary to take up the vessel again.

Mr. C. Horsfield tried this method, as recorded by Mr. Travers, in an aneurism which he performed in a patient according to a scheme, in Nov. 1818. A double ligature was passed under the brachial artery. The ligatures were first with loops or slip-knots, which a quarter of an inch of the vessel being left undisturbed between them. All that was retained of the portion of the brachial was a slight transitory motion. Sixty-six hours having elapsed from the application of the ligatures, the vessel was carefully opened, and the ligatures raised and removed without the slightest interference of the vessel. As soon then as a patient appeared the artery became distended with blood, and the pulsation in the femur was as strong as they had been before the operation. Mr. Horsfield then applied two fresh ligatures; hæmorrhage afterwards took place, amputation was performed, and the patient died.—(See *Practical Observations on Surgery*, p. 161, &c.)

Now, as Mr. Horsfield chose, to apply other ligatures on finding that the pulsation returned, the above case only proves that the artery is not obliterated in about six hours, and we are left in the dark respecting the great gloom, namely, whether the vessel would have become obliterated by the effusion of coagulating lymph and the adhesion of the vessel, and the obliteration of the system of circulation through it.

As for the hæmorrhage which occurred, I think a slight hæmorrhage existed, considering the distance and situation which the artery was once contained in the vessel, and the necessity for the application of a pressure less than four ligatures, and the removal of two of them. According to my view only one ligature ought to have been used, and none of the artery detached.

We also have an illustration of the use of ligatures which were employed; an essential piece of information furnishing a judgment of the merits of the preceding method. The application, removal, and replacement of ligatures are not constant, will not be permitted to be continued by the patient, and will not be more tedious than that recorded by Mr. Horsfield, brought on the operation of the artery, and hæmorrhage.

The basis of this work, presents us here, pointing out the particulars of the very interesting experiment conducted by Mr. Travers, upon the arteries of an animal, for the purpose of ascertaining the earliest period when a ligature might be removed, even, an artery, without any violent hæmorrhage being fully anticipated. A full detail of them may be sought for further reading, in *Med. Clin. Trans.*, vol. 4, and in a very recent, in relation to the same operation, may likewise be perused in *Scott's comments on his great work on Aneurism*.—(Scott's work on Aneurism, vol. 1, p. 112.) The cases above stated, and other observations, have been explained by Mr. Horsfield in the explanation of Mr. Jones, upon the plan of securing the ligature previously to the internal separation, which he has written in the explanation of the case of aneurism, being either an obliteration of

In favour of extirpation as a ligature, where the ends of it are to be cut off, a case published by Mr. A. Cooper deserves particular notice. The wound was found completely closed on the fourth day after the operation, notwithstanding the patient was eighty years of age. The night previously to its application was softened in warm water. The recovery was complete; a fact strongly proving the propriety of not rejecting an operation on account of age, if no other objections exist.—(See *Surgical Essays*, part I, p. 136.)

From what has been stated in the *Lancet*, however, it seems that Mr. Astley has recommended both the use of catgut ligatures, and the plan of cutting off both ends of such ligature. With regard also to silk ligatures in particular, if we take into the account the little attendance, suppuration, and hard knots, which occurred even after their use in this manner, I don't think though these complaints might be attended with no severe consequences, they will deter many surgeons from adopting the (new) mode; unless it can be proved that these disadvantages, slight as they may be, are counterbalanced by the greater healing of the incision, or some other decided benefit. As it would interfere with the most possible risk of being followed by secondary hæmorrhage, however, I consider it inferior to no practice which has yet been suggested; not on I know of any serious objection to it, at any point of view, provided exactly such ligatures are used as Mr. Lawrence recommends.

It seems it is asserted, a single small ligature, compared to Hunter's silk, silk, or catgut, is now usually preferred by the majority of the best surgeons in England; but as the right qualities of ligatures are themselves considered—on *Hæmorrhage and Ligature*, I need not here dwell upon the subject. It is not meant to assert, that the use of a single ligature is never followed by secondary hæmorrhage, for this would be untrue. The constant I believe very occasional happen after this or any other mode, under common circumstances, and in very peculiar subjects. A fact of this kind we find recorded, which happened in the practice of a truly eminent and experienced surgeon—see A. Burns on *Diseases of the Heart*, p. 223; but from the inquiries which I have made, it appears to be proved, that catgut sutures, a single small ligature, applied with as little disturbance and disturbance of the artery as possible, will be more rarely followed by secondary hæmorrhage, than any, or than any other advantage. Thus, in the several cases reported by Mr. Norriss, the single ligature was never followed by any of those inconveniences, which, he justly thinks, will be met after this practice than any other. If the artery be not removed from its situation, or more detached than the ligature separates it.—(See *Med. Chir. Trans.* vol. II, p. 123.)

Before entering into the consideration of particular aneurisms, I wish to mention a few other considerations, worthy the attention of every practical surgeon. The first is the partial extrusion of blood into the aneurismal sac, after the artery has been tied at some distance from the tumour. This was first partially pointed out, and by reasons explained by Sir E. Home, who published three examples of its occurrence.—See *Praxis de the Improvement of Med. and Chir. Knowledge*, vol. I, p. 172, and vol. II, p. 329. But the circumstance had been, I believe, been recorded with due attention, and Mr. Hodgson made a one of the subjects of his reflections in his valuable treatise.

When an artery is tied close to an aneurismal sac, the extrusion of blood into the artery is almost certainly prevented; the coagulum which it contains is absorbed, and the coagulability of which the sac is composed, gradually contract, until the cavity is permanently obliterated. But when the artery is tied at a distance from the disease, the progress of blood into the latter is not altogether prevented; for the aneurismal branches which open into the trunk, below the seat of the ligature, convey a stream which passes through the aneurism. The progress of this current, however, is so trifling that the enlargement of the sac is only evident, but the depression of coagulum if it increases, in consequence of the ligature state of the aneurism. The coagulum sometimes is in the cavity of the sac, and the result of the artery ending up is, as observed, &c.—(See *Hodgson on the Diseases of Arteries*, p. 266.)

This fact, which is of great importance, both in a practical and pathological point of view, is proved by the post-mortem, 1st, by the occasional return of aneurism in the tumour after the operation; 2dly, by cases in which the cavity of the sac has been exposed, and hæmorrhage has been the consequence; and 3dly, by dissections, in which it has been found, that the cavity of the aneurism, as well as that of the artery from which it originated, was pervious, from the part which was obliterated by the direct operation of the ligature.

For a detail of the facts relative to this interesting point the reader is referred to Mr. Hodgson's valuable publication.—P. 267, et seq.

Some very interesting instances are recorded, in which the return or continuation of pulsation at the tumour is said to have prevented the cure, the aneurismal sac having begun to enlarge again. The two cases of this kind, however, which happened in the person of Peter and Giovanni (Trans. of a Soc. for the Study of Med. and Chir. Know., vol. I, p. 172; and Journ. de la Soc. de Med., No. 2, p. 107), cannot be very depended upon, as it may be doubted, whether the artery was really tied. Some better established facts, relating to this part of the subject, have been very recently published. One is a case by Dr. Meadell, 344, of Glasgow, which is very remarkable as the disease, viz. a popliteal aneurism, occurred six months after the femoral artery had been aneurismally and in the upper third of the thigh. On the 21st of February, 1815, this gentleman performed the operation, using a single ligature; the pulsation of the tumour in the femoral artery ceased; and the wound healed by the first intention, except where the ligature was situated, which came away in the fourth day. By this time, the tumour was diminished to one-half of its original size, and in two months more, only a hard knot was perceptible, in which no pulsation whatever could be felt. After the considerable lapse of time above specified, the patient suffered by Meadell, that the tumour had reappeared, being rather larger than a plum. The pulsation in it was distinct, though not so strong as in ordinary aneurisms. At the site of the swelling and strength of the pulsation increased gradually, a compress and bandage were applied without confinement; but as this treatment was ineffectual, the patient was afterwards kept in bed, tied, and put on a splint. A thick compress was placed over the tumour, and the limb was firmly bandaged from the toes to the groin. A trial of this plan for nine days not having produced any benefit, a tight bandage was applied over the femoral, but the pain was such in half an hour, that the instrument was taken off, from which moment no pulsation was felt. Next day the tumour not only did not shrink, but had a firm feel, and the bandage being continued, the cure was gradually completed. Had the disease not yielded to these means, Dr. Meadell meant to have tied the internal or external iliac artery, with the view of cutting off the supply of blood to the sac, through the anastomosing branches.—(See *Praxis Anæsthesia*, by Walker, p. 510—522, et seq.)

The following cases were mentioned by Mr. Astley Cooper: a man underwent the operation for aneurism; the femoral artery was tied; the pulsation ceased; and the patient in a little while was supposed to be cured of the aneurism, and discharged. Upon his return he labour, however, a swelling arose in the limb, without pulsation. The swelling subsided on compression of rest; but afterwards, while the man was at work, the swelling returned with great pain. At length, as Mr. Astley supposed that there was no prospect of the limb becoming useful again, it was amputated. Upon an examination of the parts, he found that the femoral artery, below the place of the ligature, had been secreting blood. It does now and then happen (says he) that a blood-vessel will arise from the artery close above the ligature, and pass into the artery distended; below it, by which means the circulation is produced. Mr. Astley then referred to a specimen in the hospital museum, where this fact is illustrated in the brachial artery.—(See *Lancet*, vol. I, p. 268.)

The external iliac artery was taken up by Mr. Norriss, of Bath, for the cure of an aneurism, and when the collateral circulation was fully established a few days after the operation, the tumour was again supplied with blood in sufficient quantity to pro-

draw a distinct picture, "a fact," says Mr. Norman, of gradual degeneration, as it shows that though the ligament on the first morning was the direct object of being torn into the artery, and is the cause by which the disease is cured, yet that there exists a necessity for following strict rest, the antiphlogistic regimen, and, in some cases, the abstraction of blood, to assist nature in her operation of obliterating the aneurism." And to remedy misconceptions, after that some gentlemen had thought the ligament artery to be the seat of organized aneurism, the following, though escaped for a time in the former, abstracted method, is such a degree, that some doubt was entertained whether the disease would have been cured by the ligature on the femoral artery, this not imagined and rather powerful proposition being adopted.—(Med. Obs. Trans. vol. 30, p. 31, 1835, &c.)

Dr. J. Hall, in a late work, has offered some criticisms on the English method of operating for aneurism. It is hardly necessary to be so much inclined to a very partial picture of these, however, when it seems, it was so manifestly not to be fully informed of all the facts and experiments recorded in the scientific treatise on aneurism by the late Dr. Jones. "Still less excellent than we are," says Hall, "in the treatment by compression, and in the use of ligatures remedied for the cure of external aneurism, the English surgeons have immediately recourse to the operation with the ligature. Haller's method is that which they universally practice. They will not even allow, that there are any cases in which the operation by opening the sac should be preferred. And it is singular, that very wise men, whose works would induce us in some cases of aneurism, properly so called, to adopt the operation of opening the sac, is alleged by the English surgeons as a circumstance in favour of the Hallerian method. Let us suppose an aneurism so formed, that near the centre of the tumour or rather near the opening, by which the artery communicates with the aneurism, are situated the pillars of the collateral arteries, which would be usual for the re-constitution of the circulation. Here it is clear, that in performing the operation by the Hallerian method, that is to say, incising the artery above the tumour, the most rational and the most significant, but the well-known fact branches of these collateral arteries. Let there be, for example, at the upper part of the femoral artery an aneurism, which, though formed originally below the origin of the profunda, now extends above it. Here it is manifest that in trying the femoral artery above the swelling, we should lose the important position of the profunda for re-constituting the circulation in the lower part of the limb. This is an old and long-suffering the aneurism would in such a case induce us to adopt the operation of opening the sac in preference to the Hallerian method; and Scarpa himself, as gentlemen advocate for that last mode. Scarpa, who seems only to have composed his work, to cry up this method, makes an exception of the case, which I have just been mentioning. The English surgeons, on the contrary, would urge the following objection to the operation by opening the sac in this and other analogous situations. They contend that the ligature would be applied too soon to the origin of the collateral arteries, which are to receive the blood after the operation. They are possessed with the idea, that when an aneurism is fixed at a given point, the two great proximalities of the principal collateral arteries disposed to extending aneurism." &c. (p. 255, 257) A circumstance which Dr. Hall seems to deny.

Now, before attempting to reply to these observations, we ought to know what exact distance Hall means, when he speaks of the profunda, or a large collateral artery, descending near the opening by which the aneurism communicates with the main artery. How far is not small precise; and were he to fix the femoral artery immediately below the point where the profunda arises, he would expose the point to great danger of bleeding. I say this, not aware of the case which he has alluded to, given the contrary. In the aneurism being formed, he applied several ligatures (p. 256), some of which were the ligature of aneurism, or some ligatures left ready to be tightened in case of need. These were of course higher up than the ligature which was tightened. It is therefore impossible, that this last should have been close to the origin of the profunda. There must have been some interval for the application of

the ligature artery; and, as it also manifested, that the French still persist in the use of large ligatures, and not small firm round ligatures.—See Humerlins. In this part of the Dictionary we shall find that the symptoms of a collateral vessel aneurism, the symptoms of the internal aneurism, which has a natural way in the process in which the artery is closed.

With respect to the circumstances of aneurism being cured by ligature when the aneurism is placed close below, that at some distance from a great collateral artery, there occurs in a double of the first. Four years in London, with an aneurism of this kind was cured, and has published in his book. It was a case in which Dr. A. Cooper had diagnosed the artery, as the subject died of hemorrhage a British aneurism, and, as opening the body, it was ascertained that an aneurism artery, which usually arises either from the trunk of the external iliac, or from the epigastrium, proceeded from the external iliac, and arose immediately above the point to which the ligature was applied.—See Partridge in Clin. Anglo-Am. in Clin. Trans. vol. 3, p. 278, 279.

From a preparation, spoken of by Mr. Treves, and some experiments made by the same gentleman, it would appear, that the presence of a collateral branch renders the formation of the internal aneurism, as well as almost prevent the closure of the wound in the adhesive inflammation. In the preparation mentioned, a ligature was applied to the external iliac, between the epigastrium and circumflex that aneurism, and having been in contact with the femur at the angle which it makes at its origin from the iliac, aneurism had taken place, and the bleeding had proved fatal. There was no coagulum formed in the trunk, though the operation had been performed several days, the circulation through the epigastrium having continued. But the branching at the seat of the ligature in the iliac artery was complete.—(Med. Obs. Trans. vol. 3, p. 255.) Indeed, it must be allowed, with this position, that the study of the blood vessel, present the adhesive process, a fact which, however, is as proved in the indirect abstraction of a vessel, by means of a temporary ligature or compression. What, therefore, the history of a large branch in the ligature is spoken of as a circumstance contrary to secondary hemorrhage, I mean, that it is as much as the internal aneurism is itself in promoting the closure of the vessel, and its formation is prevented.

Several facts, and afterward remarks, connected, that when an aneurism was so situated, that a ligature could not be applied to the artery leading to the swelling, a cure might possibly arise from tying the vessel on that side of the tumour which was most remote from the heart. Several experiments made by this means, the circulation through the sac would be stopped, so that in it would crystallize, that the operation would go on by the collateral arteries, and that the tumour would be finally absorbed. Dissection of the femoral artery below an aneurism aneurism, but the progress of the disease, instead of being checked, seemed to be accelerated by the experiment. The aneurism transpired, in a few moments, to open the tumour, and try to close up the vessel. At this moment the patient was in some quantity of blood, and died eight hours afterward.—See Clin. Obs. & Dissert. par Boissier, t. 2, p. 262, and Systeme Physiologique de Boissier de Médecine de Paris, t. 3, No. 17.

The operation of tying the artery below the tumour was suggested by Dr. A. Cooper, but he is an advocate of the femoral artery in the groin, but he is an advocate of the external iliac, when tying the artery where the swelling was, is particularly. The femoral artery was therefore tied immediately below Pott's ligature, between the origins of the epigastrium and the profunda. The pulsation of the tumour subsided; but on progress of the disease was checked. After a time, indeed, the swelling decreased, and this is incommensurable a measure, that hopes begin to be entertained that perhaps the external iliac artery might come about of being tied above the aneurism. The tumour came away without any unfavourable occurrence, and when the wound was healed, the patient was sent into the country for the benefit of the change of air. Afterward, however, the tumour grew again, an intervention of blood took place in the aneurism and caused death of the patient, and the patient died 31.

arteria innominata. The roots of the artery, surrounding the coagulans, were thickened to about four times their natural size, and lined by a thin layer of fibrine. Above the coagulans, the roots of the artery were thickened to the extent of at least six times their natural size, and, in addition, a layer of fibrine closely adherent to the outer surface of the artery, and continuous with that surrounding the coagulans at the lower part of the trachea, there were three other layers of coagulated fibrine.—At the upper part of the thickened portion of the artery, and just above the non-ligamentous, where the ligature had been applied, was an elevated swelling on the anterior and tracheal surface of the coagulated artery a quarter of an inch in length, and rather less in breadth, covered by a coagulum of dark-colored fibrine, communicating with the opening in the trachea. This case, according to my judgment, might be reserved as another proof that Brashear's method is capable of producing those changes in the coagulans, artery, and circulation, which, if not succeeded by some accidental backward occurrence, like the ulceration, leading in this case to fatal hemorrhage, may bring about the perfect cure of the disease.

If my doubt remained of this fact after the case already cited, it would be dispelled by the results of some other fruits of the procedure, and more particularly by the history of the case of Mary Davis, aged 26, on whom Dr. Hinkle (now Professor at Anatomy and Surgery in Rutgers Medical Faculty of Geneva College, New-York) operated, under very trying and difficult circumstances, with great skill and complete success.—(Lancet, vol. 4, 1856.) The tumor extended from the clavicle on the right side upwards nearly to the axilla, pressing the trachea towards the opposite side, and passing under the sterno-clavicular articulation to nearly an inch beyond its lower border. For many days previously to the operation the patient had not been able to swallow any thing; her respiration was dangerously obstructed, and her voice faintly lost. In the operation the artery immediately above the aneurism was found dilated, not more than half an inch of its extremity being sound, and on this a single coil of ligature was placed. As soon as the artery was tied, the fibrine became softer and less compressible, and though she had not swallowed any thing for nine days, she took, before the wound was dressed, about the amount of wine and water. The operation was performed September 11th, 1857. April 16th, 1858, the woman was in perfect health. There was then scarcely a remnant of the tumor; the remarkable anorexia of the breast had ceased; and respiration and deglutition were natural. As Mr. Wardrop remarks, the facts recorded prove beyond all dispute, that we have growth of no mechanical nature may be arrested, and the disease cured, by placing a ligature on the distal side of the sac, especially if we branch of the artery intervenes between the sac and the ligature; or if a considerable branch, and one that afterwards enlarged sufficiently, were to be in this situation, the operation would have little or no effect in producing any diminution of the expansion of the blood in the aneurism, from the fainty of which the blood would pass as freely into the enlarged branch as it previously did along the trunk itself. Hence we see why Brashear's operation will probably be attended with great or success in cases less than other aneurisms, the common carotid artery giving off in its course no branch which might interfere with the principle of the cure.

Professor Hinkle being now engaged in treating aneurism and aneurism in this city, has kindly accorded me the request in forwarding me from his note-book, the following case, the principal symptoms of which are similar to this patient's, viz. in a place here. It is related in the *Lancet*, No. 244, vol. 2, May 26, 1856.

"A *chief fact* that can lead to prove or disprove an aneurismal point must be considered study of local valvular, it may not be useless to suggest a case of aneurism of a patient who in the summer of 1855, was admitted into the Westminster Medical Hospital, Dublin, under the care of Dr. Casper. His complaint was aneurism, was registered as phlegmasia of the right arm, but a large vessel being discovered in the axilla, the late Professor Todd was called to see the patient; and after careful examination he gave it as his opinion that it was an aneurism, which, from its magnitude and local situation, was to some the point, he perceived it, and found blood followed the insertion of a probe. When

passed upwards for about three inches, the valve of the sac being divided, the man was removed to the Westminster Medical Hospital, where, from a shock of any vessel consequent on the puncture, he died in a few days. Mr. Todd requested that I might examine the body, and from notes made after the dissection I abstract the following: "The aneurism, which was of large size, occupied the right axilla; the sac in some places was almost absorbed, and adhered freely to the upper and outer part of the artery; when opened, it contained large quantities of laminated fibrine, and in its centre was a cavity holding about eight ounces of coagulated blood; communicating with the artery, there was an opening of one-eighth of an inch in the axillary artery, below which the vessel was obliterated for the space of half an inch, corresponding to the situation where the sac naturally occurred.—There then was a case where the aneurism was undergoing a spontaneous cure in consequence of the pressure of the tumor having obliterated the artery on its distal side, and I took upon it as a valuable fact towards settling the nature of entering the operation of Brashear and Denham; and so much was I impressed with the efficacy, that before Mr. Wardrop published his essay, I recommended the operation in a case of large aneurism in a public hospital; but my name was to be forgotten. However, when I again met the two surgeons who so warmly collected me, it will be my turn to laugh in tears."

Mr. Wardrop himself regards Brashear's operation as too strictly applicable to aneurisms in which it is impracticable to place a ligature on the radial side of the sac, but so likely to merit the preference when the tumor is large, and likely to enlarge after no conclusion through the sac is interrupted. This inference is drawn from the fact of the immediate diminution of the swelling, which has usually followed the application of the ligature on the distal side of the aneurism. It also seems probable that in this method there is less risk of hemorrhage from the part of the vessel in which the ligature is applied than in the Brashear operation. On the principle that it is sufficient for the cure of an aneurism, and the importance of the blood through it diminished, as the deposits of laminated fibrine within the sac will then increase, Mr. Wardrop urges the propriety of extending Brashear's method to aneurisms of the axilla; aneurisms; but the very pressing and valuable cases which he has achieved in confirmation of his views of these particular aneurisms will be more convincingly noticed in the sequel. As an advance of the improvement of surgery, I must not quit this part of the subject, without expressing the conviction that sympathy of the service which Mr. Wardrop has rendered the profession and the public by his able and enlightened view of a valuable operation, which would his exertions and example might long have remained quite forgotten, or, briefly mentioned in the history of surgery and dangerous proceeding, scarcely of further trial.

[This suggestion of Mr. Wardrop has been acted upon by D. Evans, Esq., surgeon at Dulpar, Derbyshire, who successfully tied the carotid aneurism of the innominate and root of the carotid. The details of this successful operation are so convincing, that I cannot withhold from the profession the record of this highly important and successful branch of modern surgery over this most terrible disease. It is extracted from the *Lancet*, No. 271, vol. 3, Nov. 9th, 1856.]

"William Hall, aged 30, a laborer and horse-dresser, an athletic and spirited young man, about five feet six inches high, has been accustomed to laborious work, frequently rising from 70 to 100 miles a day, and has always enjoyed excellent health until the appearance of the following symptoms.—About 14 months ago he was seized with symptoms of breath, troublesome cough and tightness over the chest after much exertion, especially at walking fast to a hill.

These symptoms continued until the 10th of March, when he had an attack of hemorrhage, which he attributed to cold. The expectoration was copious, consisting of masses slightly streaked with blood, and his weight some six or seven pounds, which were followed by a sense of weakness.

On the 10th of March, after a day of coughing, a swelling appeared about the size of a walnut suddenly on its appearance behind, and extending a little above the right sterno-clavicular articulation, and

covered externally by the internal portion of the normalised intima. The aneurism was greatly diminished by firm pressure, but could not be made to disappear entirely.

The pulsation of the tumour, which was synchronous with that of the heart, was increased in force by pressure upon the right subclavian artery, and was diminished and sometimes completely arrested by pressure upon the right carotid above the tumour.

The pulsations of the right carotid and subclavian arteries were stronger than those of the left; still there was no apparent difference in the pulsations of the radial arteries.

As soon as the tumour made its appearance, the cough and dyspnoea ceased to be troublesome, and the health was soon re-established. His sleep remained well upon pressure, and the respiratory function well definitely heard all over it. No systematic pulsation could be detected by the use of the stethoscope between the tumour and the heart. A loud and powerful pulsation was heard over the tumour, unaccompanied with any tremulous sound.

In taking into consideration the situation of the tumour, its sudden appearance after a violent paroxysm of coughing, and its well pulsating character, together with the symptoms above enumerated, little doubt could be entertained of its nature, and I concluded that the root of the carotid artery was the seat of the disease.

Considering this a favourable case for the operation, I was induced to obtain the opinion of Mr. Woodroffe, lately retired, and so very celebrated by Mr. Woodroffe, I was induced to obtain the opinion of two retired surgeons at London respecting its propriety. Both, however, disapproving of the operation, it was therefore determined, with the approbation of my friends, Mr. Bennett and Mr. Brown, of Dorset, that a far more should be made of Velpeau's plan of treating aneurisms.

The nature of the disease was fully explained to the patient, who fortuitously was a man of strong sense and most determined resolution, and from his employment leading him to study the diseases of horses, there was no difficulty in making him comprehend the dangerous tendency of the disease. He therefore embarked with perfect confidence in the proposed plan of treatment, and I cannot sufficiently express the gratitude and cheerfulness with which he bore the long privation which it was necessary to enforce, and the implicit faith which he placed in all the remedies adopted for his relief.

April 3. He was accordingly ordered to bed, as he had to the extent of eight weeks every third day; his diet to consist of small quantities of gruel, broth, and tea. Small doses of digitalis were likewise administered. This plan of treatment was continued until the 13th of July. During the first month there appeared some little improvement; his pulse was frequently as low as 47 in the morning, the tumour became harder, its pulsations less frequent and more prurient; those which it was supposed that coughs might be hearing. The blood吐eritis had become seriously healthy, and it was noticed that if the bleeding were delayed beyond the usual time, the symptoms were aggravated.

In the beginning of May a great attention to the worst took place, which was supposed to be owing to his taking a small quantity of animal food. The blood after each bleeding became buffed, pulse 80 in the middle, the tumour slightly increasing in the course of a few days, and becoming very painful upon pressure. Twenty leeches were applied without any effect. A few days afterwards a diarrhoea supervened, the inflammatory state of the tumour abated, the pain ceased, and the swelling in some degree subsided. After this much his pulse was never less than 60 in a minute, although the same plan of treatment was rigidly adhered to.

From this time until the 1st of July the tumour remained stationary; but from the latter date until the 20th he gradually got worse, the tumour increased, and was reached as high as the crooked cartilage, and by its pulsations upon the trachea and mediastinum partially impeded respiration and deglutition. His stercoraceous, which, prior to his illness, would have been constant, ceased and now he made to meet by more than three times; his countenance became flushed; pulse more feeble; and it was evident that the lowering system had been carried as far as it could with safety.

Under these circumstances the operation was recom-

mended as the only remaining chance. Its advantages and disadvantages were fully stated, and the chance of success, although small, made him anxious that it should be performed. Dr. Bennett, of Dorset, saw the patient on the 11th, and concurred in the propriety of the operation as a last hope.

On the morning of the 23d of July, the day proposed for the operation, the patient became so anxious that the pulsations of the trachea, of the heart, and the large arteries, especially the subclavian, were well perceived by the eye. The operation was performed in the presence of Messrs. Bennett and Brown, of Dorset; Mr. High, of Ashby-de-la-Zouch; and Mr. Walter, of Chancery Lane, surgeons.

In consequence of the tumour extending as high up the neck, there was some difficulty in getting down to the sheath of the artery, which was opened to the extent of half an inch. The artery appeared healthy, and was easily secured by a single ligature of strong silk.

Immediately after severing the ligature the pulsations in the different branches of the subclavian carotid artery ceased, except a slight fluttering in the extreme branches of the temporal. The pulsation of the carotid continued without diminution.

24th. Both. He went on well. The pulsation in the trachea was stronger than it was before the operation, and the pulsation of the right radial artery was observed to be more forcible than that of the left.

25th. He became feverish; pulse 120, and full; the right leg of the wound swelled and painful. Six ounces of blood were taken away from the arm, and some saline medicine administered. The blood was much buffed.

26th. Morning. Much better; pulse 92, stronger in the right radial artery than in the left; pulsation in the trachea still very forcible.

Evening. The fever and pain in the wound returned. He was again bled. Blood still buffed.

27th. Better again this morning. He was taken twice at nine o'clock in the evening. Pulse 100; delirium; anxious countenance and sickness. No distinction in the size of the tumour.

28th. Much better, and continued so all day.

29th. At seven a. m. he was taken suddenly worse, and appeared to be dying; his countenance ghastly, and covered with perspiration; tracheal rattle, and inability to swallow. He appeared comatose, but could only speak in a whisper; pulsations in the trachea still forcible; the pulse in the right radial artery scarcely perceptible, while the left pulsated as strongly as it did the previous day. These symptoms were accompanied with a profuse perspiration. He remained in this state for several hours, at the expiration of which time he rallied; and by the evening (with the exception of the salivaceous, which continued) he appeared quite as well as on the preceding day.

As he continued to improve from this period, it will not be necessary to enter into a daily report of the case. I shall therefore confine myself with noticing the most prominent symptoms which occurred. One of the most remarkable was the obliteration of the arteries of the right arm and forearm, which was first observed in the arteries of the forearm on the 13th of July, the eighth day after the operation; for until that day the arteries of the right arm pulsated with greater force than those of the left. The process of obliteration was attended with severe paroxysms of pain, chiefly felt in the course of the brachial and axillary vessels.

The brachial artery after its obliteration was hard and painful to the touch, and felt very like an inflamed abscessed vessel. The right arm wasted, and became gradually paralyzed, and continued to diminish for three weeks; at the expiration of which time several uncomfortable breeches were observed pulsating on the back part of the arm. As these vessels enlarged, the limb improved very slowly, but having yet (18th) perfectly acquired sensation, nor its previous power of obeying motion.

On the 11th day after the operation, he was attacked with interesting paroxysms of pain in the right side of the head and face, of the same character as the pain in the right arm, though not so violent; this pain ceased within a fortnight. The right side of the head and face became emaciated, and very few looking at him would immediately discover that the right half of the face was much smaller than the left. The blood having since found its way into the temporal and facial

the same success (vol. vi. p. 37), and a case in which thrombosis effected a cure by compression: the femoral artery by means of an instrument applied just above the place where thrombosis produces the closure of the disease, aneurism is treated by Bandeau.—(Fr. Journ. of Med. Bandeau's work, t. i. p. 314, 315.)

The aneurismal tumor which the rupture of a transverse aorta affords the first stages of aneurism have been already mentioned, as well as the presence of aneurism in the placenta, perfect aneurism, Venous aneurism, aneurism of the heart, and other aneurismal affections, especially in, which was first communicated by Richard Meigs, and subsequently (Widd) proved by Rokitnik.

Aneurism, in general, and among them the popliteal aneurism, are attended with some of the signs of a spontaneous cure, yet also denote a want of the cure: it is in a false way, rather for the purpose of the operation, especially as it is the usual source of the disease to continue in progress; while in the early stage the cure may be more speedily accomplished. In fact, the experience of modern operators leaves no room for supposing that the aneurism will not suffice for the due treatment of the leg, and consequently prove that waiting beyond a certain time for the cure of the popliteal aneurism to take place is altogether an unnecessary and disadvantageous method. Popliteal aneurism, as well as other cerebral aneurisms of the same nature, attend the first stage of a spontaneous cure, when any other disease is general, violent, and deep inflammation all over the body; for then the communication between the sac and the artery is likely to be closed with coagulating lymph, and the pulsation of the tumor to be suddenly and permanently stopped. If in this state the disease deepens, and the patient's constitution fails, the coagulated mass in the sac and the thrombus are gradually detached, leaving a deep ulcer, which ultimately heals. An example, in which a popliteal aneurism was cured by such a process, is related in the *Trans. for the Improvement of Med. and Chirurgical Knowledge*, vol. 3, p. 316.

In former times, when all hopes of curing a popliteal aneurism by Talbot's method, by compression, or a natural process, were at an end, surgeons of the high was considered as the safe and necessary means of saving the patient's life. But about fifty years ago, the confidence of surgeons in the efficacy of the compressing means or the contraction of the stricture began to increase, and, in opposition to the tenets of J. L. Petit and Pott, experience was proved, that in general, not only might the patient's life be saved, but his limb also, and this without any operation that could be compared with amputation in regard to safety. On looking back to the history of aneurism, we shall find that A. N. Garengeot was one of the earliest writers who disapproved of amputation as not truly indispensable for the cure of popliteal aneurism.

It is alleged that Teislere, Myrdell, Goussard, Maubert, and some other celebrated Italian surgeons, were the first who refused to be the popliteal artery for the cure of aneurism. The path, as Pelisson remarks, had been pointed out to them by Winslow and Halber, whose valuable description and picture of the arterial aneurism about the knee-joint, showed by what means the lower part of the limb would be preserved, while the upper had been placed in the principal arterial trunk. For almost thirty years, however, the opinion of treating the popliteal artery was confined to the Italian surgeons. Philippe Rivier held the view that the first was attempted took its origin at Paris nearly thirty years ago (relating to about the year 1780) the *Journal Chirurgical* being dated 1810.

However, the operation of opening the femoral and tying the internal artery itself, was a severe and often fatal proceeding, and even not aware of being compared with the Hæmorrhoid operation in most cases of aneurism, many of aneurism, as I shall explain, after the time of a few particulars relating to the popliteal aneurism.

On the lateral side of the artery the thrombus is produced, it can be easily felt in the hollow between the hamstring, and as general its nature is as easily ascertained by the pulsation in every part of the femoral. Though the disease may not occur in the popliteal artery as often as in the same limb it certainly is seen more frequently in the femoral region than any other branch which the artery sends off. As Dr. J. Home

has observed, this circumstance has never been satisfactorily explained; and, what is rather curious, in many recent instances of this disease the patients have been mortally and positively. Morgagni found aneurisms of the aorta most frequent in glands, psoas, and other persons who sit almost wholly on horse-back; a fact, which he ascribes to the concussion and agitation to which such persons are exposed. Some allusion to this subject has already been made in the foregoing pages. Whether an explanation of the frequency of popliteal aneurism can be correctly referred to the alteration which the circulation in the artery itself experiences when the limb is in a state of flexion, may be questioned, though it is on a similar principle that the great frequency of aneurism of the carotids of the aorta is attributed to be solved.—(Hence in *Trans. for the Improvement of Med. and Chir. Knowl.* vol. 1, 4, 5, and *Notes in Ed. Med. Essays* vol. 5.)

Were this the only, or even the principal cause, surely one would have reason to expect aneurism to be at least as frequent in the axilla, and in the bend of the elbow, as in the knee.

The popliteal aneurism was generally supposed to arise from a weakness in the coats of the artery, independent of disease. If this were true, we might reasonably conclude, that except in the distal part the vessel would be sound. Thus the old practice of opening the sac, tying the artery above and below it, and leaving the bag to exsufflate and heal up, would naturally present itself. As the arterial coats were found to be altered in structure higher up than the tumor, and the artery manifestly above the sac seldom failed when tied, that when the ligature came away, the patient was destroyed by hæmorrhage. Mr. Hunter concluded, that some disease affected the coats of the vessel below the natural occurrence of aneurism. Dissatisfied with Haller's experiments on frogs, showing that weakness alone could give rise to aneurism, he tried what would happen in a quadruped, whose vessels were very similar in structure to the human. Having divided above an inch of the carotid artery of a dog, and removed its external coat, he dissected off the other coats, layer after layer, till what remained was so thin, that the blood could be seen through it. In about three weeks the dog was killed, when the wound was found closed over the artery, which was neither increased nor diminished in size.

It being conjectured that the prevention of aneurism, perhaps arose from the parts being incessantly laid down on the weakened portion of the artery, Sir E. Jones stripped off the outer layers of the femoral artery of a dog, placed first over the exposed part of the vessel a piece of flannel, and then the sides of the wound, and in six weeks killed the animal and opened the artery, which was neither enlarged nor diminished, as often having replaced their natural thickness and appearance.

These experiments strengthened Mr. Hunter's belief that structural arteries are diseased; that the natural affection frequently extends a good way from the site along the vessel; and that the cause of failure in the old operation arose from tying a diseased artery, which was incapable of tightening before the ligature was removed. Those authorities led him to propose taking up the artery in the healthy part of the thigh, as were distant from the diseased portion, so as to diminish the risk of hæmorrhage, and to enable to get at the vessel again in case it should bleed. The success of blood tied into the sac being stopped, he concluded that the sac and its contents would be absorbed, and the vessel gradually disappear, so as to render any opening of it unnecessary.

Dr. David Hewson was the first surgeon who performed this operation in America, which he did successfully as early as 1808. Three cases of aneurism were cured by him, by the ligature of the internal artery, and will be found reported in his valuable volume of "*Essays on Medical Science*," by which it will be seen, that this distinguished physician in the latter part of his life was an ardent supporter of more than ordinary skill. The two science devoted labors, in teaching the theory and practice, and in the most extensive character of a general practitioner has acquired a reputation second only to Rush, with whom his name will be transmitted to posterity as being the most eminent in their profession in this or any other

the wound. Scarpa's reason for this practice is to avoid the necessity of removing the sartorius muscle too much from its position, or of turning it back, to bring the artery into view, so as to be tied. I have seen the best operators, even professors of anatomy, embarrassed by having the sartorius muscle immediately in their way after the first incision; and as the vessel is more superficial a little higher up, the plan is further from the divided part of the artery, and there is no hazard of the anastomosis failing to keep up the circulation. This part of Scarpa's practice is highly deserving of imitation.

The part of the artery (observes Mr. Hodgson) in which the femoral artery can be tied with the greatest facility, is between four and five inches below Poupart's ligament. The profunda generally arises from the femoral artery in such a way as to be an inch, and three-quarters below Poupart's ligament at very nearly right angles to the main trunk. It therefore, the ligature is applied to the femoral artery at the distance of four or five inches below Poupart's ligament, the surgeon will not be embarrassed by meeting with the profunda during the operation, and the chance of causing secondary hæmorrhage, by tying the artery close to the origin of this vessel, will be obviated.—(On the Diseases of Arteries, &c. p. 431.)

The incision being, however, too low down, so as to have the sartorius intervening between the external wound and the artery, may be more accurately estimated, when it is known that Desault, in the treatment of this aneurism, considered it right, actually to make a complete transverse division of that muscle, a thing which, it is said, may be done without any ill consequences.—(Rogee, Traité sur Mal. Chir. t. 2, p. 105.) I shall not presume, however, to record this last piece of advice, because, though it may have been done by Desault, it appears to me that the artery can always be taken up very well without the preceding last measure being used.

A few years ago Mr. C. Blandin published a paper, in which he advocates for the practice of making the incision at the outer edge of the sartorius, and then raising that muscle and drawing it upwards, in order to bring it to the artery. This advice proceeded from the apprehension that the plan of taking up the femoral artery at the inner edge of the sartorius was attended with risk of injuring the profunda vein, and large hæmorrhage.—(Lectures on the Operation for Popliteal Aneurism, 1811.) The same method is recommended by Hager and Boerhaave.—(Observations Med. sur le cancer, t. 1, p. 125) when the aneurism is done low down in the thigh. But in operating in this situation is liable to the several objections of approaching too near the distance of avoiding taking up the artery where it lies close to the bone, that it does higher up, and of every inconvenience which may arise from the incision, dissection, and reflection of the sartorius muscle, the method must be rejected, unless it can be proved that so many disadvantages are fully counterbalanced by other considerations. If the plan which I shall presently recommend be adopted, there will never be the slightest risk of wounding the profunda vein; and, therefore, I do not consider it advisable or necessary, for the avoidance of this accident, to make the incision precisely upon the sartorius, as my intelligent friend Mr. Hodgson suggests; a method attended with the inconvenience of having the fibres of that muscle between the external wound and the artery, and perhaps inconsistent with the excellent directions which he at several deliveries concerning the right mode of performing the external incision, when he says, with Scarpa, that this cut should be “continued down to the bone, which from the inner margin of the sartorius.”—(On the Diseases of Arteries, &c. p. 431.)

Now, if the point where this margin first lies over the artery be the proper place for the lower incision of the external incision, we shall clearly be deviating from the precise course of the vessel by letting the higher portion of the incision be over the fibres of our muscle. And when it is further reflected, that the serious risk of wounding the trunks of the lymphatics in this operation are not demonstrated in modern practice, while the profunda vein may always be avoided with certainty and facility, I cannot admit, that there is any solid reason for letting the position and direction of the external wound be determined by such apprehensions. At all events, for the reasons

above explained, it should be a fixed maxim in this operation, never to extend the wound lower than the point where the inner margin of the sartorius crosses the artery; and from all conclusions and displacements of this muscle will be unnecessary, and every circumstance which might proceed from its interposition between the outer wound and the artery, will be completely avoided.

With the view of preventing injury of the femoral vein, Mr. Camichael recommends the needle to be introduced on the outer side of the artery, where the vein presents itself to view, and can be most easily avoided. He remarks, that the only part of the thigh from Poupart's ligament to the level of the trochanter, in which the femoral vein is not completely covered by the artery, lies within the space which extends from Poupart's ligament to the point where the artery meets the sartorius muscle. At the part of this space most distant from Poupart's ligament, the vein begins to become small at the point-side of the artery, does not branch, and it emerges more and more as it ascends.—(See Tronc, &c. of the Femoral, &c. of the King's and Queen's College of Physicians, Ireland, vol. 1, p. 325.)

The skin and cellular membrane must be divided in the situation, and to the extent above specified, down to the femoral fascia, under which the artery lies, and may be felt beating. The next object, therefore, is, to divide the fascia, which is here with thicker than at the outer side of the thigh, and may be cut with some care close to the artery; or (which is safer, with the view of abstracting from all chance of wounding the artery,) a slight cut may first be made in the fascia, the division of which may then be made to the requisite extent by withdrawing under it a pointed dissection, on which the further incision may be made with perfect security. The fascia is to be divided in the direction of the external wound; but to what extent, is a point on which surgical writers differ, and, indeed, they must here differ, so long as they are not unanimous about the method of applying the ligature round the artery; because if it is intended to use a ligature, with a cylindrical piece of linen interposed between it and the artery, or especially if it be designed to apply two ligatures and divide the vessel in the interposition, more of the fascia must be exposed, and of course more of the fascia must be cut, than when it is simply meant to surround the vessel with a single annular ligature. Both opportunities are here suggested, the pernicious habit of isolating the artery all round, without any to be then thrust their fingers under it, will likewise require an extensive opening of the fascia. This dissection of the vessel for an inch or more, for the purpose of placing the ligature under it, is a measure which deserves to be considered in the strongest terms, as it is the very thing which produces some risk of injuring the profunda vein, and has a tendency to bring on secondary hæmorrhage, inasmuch as it is essentially unnecessary lacerating, stretching, and distending of the artery and surrounding parts, and an inevitable division of the vessels by which the arterial canal is supplied with blood.

According to Mr. Hodgson, the extent of the cut in the fascia should be about an inch; he is wholly devoid of all unnecessary separation of the artery from its surrounding parts. On the contrary, Scarpa, who contradicts and proves the vessel, generally to hang its loose part upon the profusion of cutting the fascia the whole length of the external wound; for, says he, if this practice be neglected, it most frequently happens, that in the succeeding inflammatory stage, the bottom of the wound swells and becomes very tense, and the matter which is formed under the fascia, not finding a ready exit, sometimes abscesses which seriously retard the cure. But Scarpa, instead of planning a method of relieving the consequences, might have surprised him self were he the purpose in considering how they were to be prevented, and why is his method they most frequently happen. Now, without lagging any more upon this wanted ligature, such composed of six threads, with an additional catgut suture between, viz. a roll of linen, in the course, we should be more surprised to hear that the wound after his method did not become affixed with swelling, tension, and suppuration, than that these were the usual effects. After describing the division of the fascia, he observes: “With the point of the fore-finger of the left hand, strongly touch-

ing the femoral artery, the aneurism will separate at first the radial or subclavian, which sits at internally and posteriorly to the subclavian vessels; and making the point of the artery itself pass gradually under and behind the femoral artery (supposing the aneurism has not uncommonly long projected), he will raise it above from the bottom of the aneurism, or (what is found to succeed) slide with the femoral vein. If it sliding with the femoral vein, the aneurism, hold, one the artery and pass this round, and almost out of the wound, then externally separate the vein from the artery with a knowledge of position, or simply with the finger. *See on this subject a dissertation, p. 260, ed. 2.*

When we consider the irritation and mischief of all the weak vessels in effects of blood, the bottom of the wound with out it, I would ask, what unnecessary passages through any other person have suggested by bringing on the suppurative state of the wound which for centuries as well frequently taking place?

I shall suppose the aneurism has not been divided, in order which the surgeon continually feels the pulsation of the femoral artery, which is still, impeded by the cellular sheath. The femoral vein has directly under this vessel, while the pulsation of the anterior cranial nerve, separated from it by dense cellular substance, are more externally, yet somewhat more deeply situated. The next object, therefore, is to pass a single ligature round the artery, without including, or in any manner meddling with, the adjacent blood vessels, or extending and disturbing the artery. For this purpose the best direction is now given by my friend Mr. Lawrence, especially when combined with Mr. Carcass's plan of leaving the needle be introduced on the paler side of the artery: "after directing down to the artery, a slight scratch or incision may be made through the sheath, close to the side of the wound. Then, with a narrow aneurismal needle, partly pointed at the end, and made so thin at its eye as it can be without cutting, a single silk ligature is to be conveyed round it, the point of the needle being kept in contact with the artery. A needle of this form makes its way easily through the cellular substance, and the vessel is detached only by the track of the instrument." (*See Med. Clin. Trans. vol. 6.*)

If the kind of ligature to be employed, I need not say here, that it should be a single one composed of fine materials, in order to avoid the necessity for excising its filament near where would be desirable for persons elsewhere considered.—*See Memorials and Ligatures.* The ligature having been put under the artery, one end of it is to be drawn completely through the track made for it by the needle, which instrument is then to be taken away, leaving the ligature under the vessel. The ligature is now to be tied in a steady, firm manner, but without any excessive force, which can never be necessary even for the division of the artery some of the vessel. In this part of the operation, a few practitioners give the preference to what is termed the surgeon's knot; and commend the plan of leaving the ligature a plan which consists in passing the end of the cord over through the aneurism, under the constriction as made. The only good of the surgeon's knot is, that it does not so readily slip and loosen as a common one; but Scarpa thinks a single knot best, as it does not, like the other, prevent the surgeon from catching the fibre with which the artery is connected.—*See Memorials, p. 20, ed. 2.* And besides the knot around the surgeon's knot, another operation is to be the irregularity with which a ligature with the force will round the vessel. A single loose slip of thread is first made and tied round, and then a second one, so as to form a second knot; and now, as a matter of precaution against the possibility of the ligature slipping and loosening from the surgeon, if the patient, can tie the knot once more. One end of the ligature is now to be cut off near the knot; and the sides of the aneurism are to be brought together with strips of adhesive plaster, the division of vessels being carefully avoided. The remaining end of the ligature should always be brought out at the external point of the external wound in the knee of the artery.

The effects which in general immediately follow the operation are, a suppuration of the part, or of the aneurismal sac; a suppuration usually, and therefore of the swelling; a fluctuation in pain, which is not

the failure; and a strong vibration of the aneurism as it is moved round the knee. As Mr. Hodgson has remarked, the natural influx of blood into the aneurismal sac, when a small artery is suddenly aneurismal, is generally attended with a considerable increase in the temperature of the part. After tying the femoral artery for the cure of popliteal aneurism, the same phenomenon occurs, so that after a short time, during which the temperature of the leg and foot frequently continues lower than that of the sound limb. But in a few hours it generally rises, and is sometimes several degrees higher than that of the opposite limb. This state lasts several days, at the end of which time, the heat of the limb which has been operated upon will be found to be about the same as that of other parts of the body.—(*Memorials, Dissertation of Aneurism, p. 258.*) It is only while the limb is colder than natural, that it ought ever to be freckled or covered with flannel. In particular examples, there is an increase of temperature in the limb, at any period after the operation; a heat which Mr. Hodgson ascribes to the probability of a venous circulation having already been established in consequence of the obstruction to the passage of the blood through the femoral artery; by the accumulation of the circulation in the aneurismal sac. Of course, unless a collateral circulation be established, the aneurism cannot succeed, as the limb will mortify; it follows me, therefore, to be aware of the circumstances which may prevent the transmission of the blood to the aneurismal part of the limb. These are fully explained and enumerated upon in Mr. Hodgson's work: 1st. An extensive inflammation, by which the principal anastomosing branches are divided. 2dly. Tight ligatures and pressure operating so as to obstruct some vessels. 3dly. The intense heat of the tumour, and the pressure upon the principal anastomosing arteries. 4dly. Callosities depositing in the coats of the arteries of the limb. 5dly. Advanced age. A languid state of the circulation, a fact indicating the weakness of venous action, as a general practice after the operation, though it may yet be right to adopt this treatment, where the pulsations return in the tumour with increased strength, and appear to stop the discussion of the swelling, as already mentioned. 7thly. The absorption of heat from the limb by cold evaporating lotions; a plan which can only be right when there is a good increase of heat in the limb, a tendency to inflammation, or a return of other pulsations in the tumour.

So Asley Cooper uses a cloth which the application of seawater occasioned mortification and the patient's death. In cold weather, he always covers the limb with flannel or a stocking, and sometimes puts powdered with hot water to the foot.—(*See Memoirs, vol. 2, p. 42.*)

When the operation is done according to the principles laid down in this article, the patient is not too old, nor unduly, and the after-treatment is properly conducted, mortification cannot now be said to be a frequent event. In one case, reported upon by the Asley Cooper in 1821, the whole of the face and part of the leg mortified; but it should be noted, that in this instance the whole limb was extremely swollen previously to the artery being tied.—(*See Memoirs, vol. 2, p. 43.*) In all his extensive practice, he has seen but three or four instances of a slough of the operating integuments.—(*See Memoirs, vol. 2, p. 43.*) Mr. Cooper has related one example which is described in the appendix of an account with hot and water.—(*See Memoirs, vol. 2, p. 43.*) As, however, the aneurism never so large from a very oblique diameter, and to have been treated with intussusception of other parts, the reality of the slough seems to me highly likely. I have seen but one example of gangrene, and in that, only one toe, and a portion of the skin of the aneurism, occurred in a very detached subject. This painful progress of the foot has been particularly noticed by Deschamps and Scarpa, the latter of whom remarks it as an unusual thing, only likely to happen in old, weak, or naturally debile; and "as any rule (says he) if it should happen in any of these persons, the patient may prevent it by using themselves for the foot of one or two of their toes, with the view of a partial amputation, and the treatment of a partial and detached aneurism in the knee, and of the intussusception which would have followed it."

So Asley Cooper has known instances of gangrene brought on by the operation in one or two examples, and the toe

of the effusion is indispensable.—*Edinburgh, &c. vol. 3, p. 26.* Mr. L. first cut with a razor to which the aneurism artery divided below the profunda, the two open vessels, the most superficial of which was a thick natural and soft in the operation. The patient died of constitutional debility, arising from indigestion in the whole course of the cure. After two or three days, the pulsation of the tumour, which had been very strong, ceased; it was thought of its absorption in the blood within the six (another fact, some say, that this desirable change will not be prevented by a vessel of blood being introduced into the aneurismal cavity).—(*New Quarterly Journal, vol. 2, p. 167.*)

Mr. Lisson has recorded a case, in which the pulsation and tumour returned several months after the operation. "On consulting with Mr. Thomson, it was agreed to try the effect of methodical bandaging, from the point of the toes upwards, and a compress over the tumour, with rest, cold applications, and moderate diet." These means had the desired effect, and the patient did not complain much of three years, which is frequently remark after the operation for aneurism.

According to Mr. Lisson, these vessels are in general directly referable to the sympathetic nerve, and its branches, and are explained by the state of the vessels in the substance of the nerve. "In the natural state the arterial vessels, when injured, are as large as a writing quill; but when the replacement of the natural branches is requisite, owing to the obstruction of the trunk, they also are called on to contribute their share to the new circulation; and they become extremely distended. In one remarkable instance, in which the limb was injured and exposed fifteen years after the vascular fracture, very bad lesions occurred far removed from the limb, the vessels in the sympathetic nerve had attained the size of cranial quills, and were convoluted in an extraordinary manner. The pulse in the limb, noticed by Mr. Lisson on coming after the operation, he acknowledges, however, are by no means so severe as those experienced previously, and which are produced by the compression and stretching of the nerves by the scar."—(*Edin. Med. Journ. No. 34, p. 2.*)

When the operation succeeds, a considerable portion of the artery above the aneurismal tumour is rendered impervious, the vessel indeed being sometimes converted into a solid cord, and some of the profunda to the of the iliac arteries.—(*J. Cooper, Med. Cas. Trans. vol. 2, p. 251.*) In practice, however, the obliteration of the artery is less extensive; a fact particularly noticed in one of Mr. Hunter's cases (*Tracts of a Society for the Improvement of Med. and Chir. Knowledge, vol. 1, p. 155*), and wisely argued by Blandin as a result of the insufficiency of the new method. (See observations of Blandin on the Ligature des principales Arteries Majeures, et particulièrement sur l'artere aorte, *Chir. Expérimentale, p. 36, Paris, 1787.*) It appears from the observations of Mr. Hodgkin, that the artery generally becomes impervious, by the spine of lance or four fingers' breadth, at the place where the ligature is applied; below which part it tube is applied, and continues so far more distally, when the obliteration again commences, and descends along a considerable extent of the posterior artery to the origin of the inferior iliac, or iliac arteries. Thus, says this author, an isolated portion of the femoral artery presents its cavity, from each extremity of which considerable communicating branches arise; the upper branch is carried along into the vessel, and the lower towards it, and communicating branches, that originate below the knee.—(*On Diseases of Arteries, &c. p. 476.*) Now, as Mr. Hodgkin is unacquainted with any more, except that recorded by Sir Astley Cooper, where, after the vessel was cut, the artery was collapsed from the point of division at the knee to the part in which the ligature was applied, he thinks it probable that, in some instances, a more natural situation exists in the artery, after this method of cure.

In consequence of the system of the blood being more or less impeded in the sympathetic way by the application of the ligature in the femoral artery, the aneurismal cavity soon becomes completely filled with coagula, which even block up the venous portion of the aneurism. The coagulated blood in the sac is afterwards absorbed; and a partial destruction and final disappearance of the aneurism of the new mode; with the exception of a slight induration, which sometimes

remains, composed of a remnant of the sac itself, or of the fibrous part of the vessel. These slight indurations in the cavity of the limb, sometimes are imperceptible, and does not hinder the patient from performing the manœuvre of the knee and leg with quickness and safety.—(*Cooper, p. 255, vol. 2.*)

After the operation, the circulation is carried on principally by the anastomosing vessels, which branches communicate with the articular arteries of the popliteal, and with arteries sent to the knee by the anterior and posterior tibial. Large branches in the sciatic nerve, sent off by the aneurism profunda, communicate very freely with the popliteal artery, the anterior, and branches of the posterior tibial. As Sir Astley Cooper has further explained, the freedom of anastomosis between these is a description of an aneurism. The femoral artery was tied by Mr. Key, and the patient, after being disengaged, returned with a painful tumour in the knee, attended with excessive tenderness. The limb was swelled, and a large artery, passing to the tumour, and inserted nearly in the usual place of the normal, forming a ligature.—(*Lectures, &c. vol. 2, p. 161.*)

When the advantages of the foregoing method of operating are contrasted with the dangers and so many of the practice of laying open the aneurismal tumour, and applying ligatures round the distal part of the vessel, it is surprising to find any living surgeon still exposing a patient to the latter mode of treatment under any circumstances whatsoever. Yet Boyer, Roux, and a few of the modern French surgeons, are in this way of thinking, which reminds me of their slow-witted, at every opportunity, when by the first operation, on the greatest and most decided advances to perfection ever made in the practice of surgery. The severity and difficulties of the old method of operating, in cases of popliteal aneurism, are most fully depicted by Cooper. In the knee, says he, the artery lies very deep. The space is limited and narrow, within which it is brought into view and tied, without risk of lying along with it, or of destroying some of the principal businesses formed by the articular arteries of the knee. In account of the depth of the artery, it is difficult to pass any instrument round it, without touching other parts; and it is no less difficult to trace the ligature on the vessel with a proper degree of lightness. Scarpa then represents the distal part of the artery as the narrowest, divided part of the vessel, which is sometimes so high up, that, in order to apply the ligature above it, it is necessary to cut through the long head of the triceps, and make a passage through into the thigh, or, the distal or lower part of the artery is situated so low down in the calf of the leg, that it is impossible to avoid touching, either in the incision or the ligature, the lower anastomosing articular arteries, or the preservation of which the circulation and life of the subsequent part of the limb is a most delicate affair. We must add to all this the violent convulsions, which are the great venous nerve, which an assistant must hold drawn to one side of the wound, nearly the whole time of the operation. The proceeding is also liable to other great difficulties, as may be seen from a case reported by Malatti (*Ann. and Anecdotes, p. 34*), where the popliteal artery was so firmly tied, and, as it were, confused with the vein, the nerves, the tendons of the neighbouring muscles, and the pulsations, that the cavity of the limb presented the appearance of an interlacement of parts, and every separate body and its order. Lastly, the operation leaves a large deep wound, lay open the whole cavity of the knee, and followed by great suppuration, abscess, and formation of the heads of the bone and joint. If the patient be not terrified into the progress by these difficulties, and even if the parts in the limb heal, he is still always left with an irreparable weakness of the knee, and perpetual lameness. Thus, Malatti (*ib. cit. p. 37*) relates one case, where the subsequent effect related with destruction of the soft parts in the knee, that not a vessel of artery, vein, or sciatic nerve was left, and the patient remained all the rest of his life with a paralytic leg, and a severe and fatal ailment to the knee.—(*Cooper on Aneurism, p. 251.*)

I shall now advert to a few facts in the history of surgery, which evidently led to the bold and successful operations adopted at modern times for the cure of aneurisms of the femoral and popliteal arteries. The earliest case of which the particulars are recorded, amounting to a satisfactory proof that the former extremity might be duly supplied with blood, notwith-

standing the femoral artery had been tied high up in the thigh, is the example related by M. A. Borelman of a false aneurism of the thigh, about right finger's breadth below the groin, caused by a gunshot wound. In this instance, Borelman tied the femoral artery above and below the aneurism in it, and not only was the patient's life saved, but the use of the limb also preserved.

(*Chirurgie Algérienne*, p. 2, *Épistémologie*.) The most authentic case of the ligation of the femoral artery, is that reported by Rivière, where Borelman, in 1698, tied the artery on account of a false aneurism, the wound of a sword-wound, at the lower and upper part of the thigh. The surgeons called into consultation were immediately convinced, that the only thing to be done was to take up the femoral artery; but they were instructed the artery should perish of bleeding ere the opening in the vessel could be bound; and in order the artery were secured, they speedily effected the destruction of the circulation would be followed by mortification of the limb. The patient was therefore first prepared for his fate by the administration of the narcotic. A band was then applied round the upper part of the thigh, and infected by means of a stick with which it was twisted, a piece of quassia being put under the hand, in order to render the constriction less painful. The incision was then opened, the clotted blood extracted, and the opening in the artery detected by introducing the finger. A curved needle, armed with a double ligature, was then introduced under the femoral artery, and one of the ends was tied above, and the other below the wound in the vessel. Then follows a curious passage, showing the surgeon's judgment at that time, respecting the propriety of interposing any cylinder of linen between the knee of the ligature and the artery, in case of the old surgeons at that time used to do, as well as a few of the moderns. "*On ne put point de mettre entre eux un tige de linge, ni d'écarter le point compressif car le sang de l'artère ne cessait de couler, comme font quelques uns, parce qu'ils jugent qu'il doit d'écarter grande importance de leur traitement sans savoir à cause de cela, et que l'on n'aurait pu le voir de faire un entortement à petit compresse, &c.*" For greater security, assistants who suffered each other in turn kept up constant pressure on the tied part of the vessel for twenty-four hours. In six weeks the patient recovered, and afterwards enjoyed such good health that he went through several campaigns. (*Journal, Mémoires, Recueil des observations Clin.* 169, 170, *Chim. Paris* 1702.)

Now, with respect to these two cases, it merits attention, that though Rivière, Morgagni, and others, endeavored to explain the success, by supposing that such of the patients in question must have had two femoral arteries, both Borelman and Rivière were wise enough to avoid making any such erroneous inference themselves. At a later period, Gualtieri has been the femoral artery, as it passed under Poppert's ligament, compressed it against the margin of the pulley, by means of graduated compresses retained with a wire roller, and thus obtained the speedy obliteration of the vessel, and cured the aneurism, which had been first spontaneously opened. (*De Extremis Arterio-vascularibus*, 1715, 1716.) In the same book is given the case of an internal aneurism, which, when it had continued three months, and become equal in size to a large pea, was attacked with gangrene, whereby the aneurism was quickly destroyed, and the femoral artery was obliterated for a considerable extent from the point such denervation. The aneurism nevertheless left, however, and the ulcer had a great inward leak, when the patient fell a victim to debility. (*Ibid.* 17.) Here it is to be remarked, that during the five weeks this man lived after the obliteration of the femoral artery above the origin of the profunda, not only the circulation and life of the whole limb were preserved, but the auxiliary arteries, issuing from within the pelvis, proved capable of sustaining the progress of the nutrition of the parts past the aneurism, and of counteracting the heaving process as a disease which caused great signs of a cure. A similar fact is also recorded by Dr. Clarke. (*Medical and Comment.* vol. 2.)

In cases of aneurism in the thigh, it is not always practicable to decide with absolute certainty whether the disease is situated in the femoral artery, or in the profunda; and even when it is apparently contiguous with the former, the latter is often deeply involved, particularly when the disease has been of long standing.

Many unsuccessful cases have been reported; and I know of one which has failed in the hands of a skilful and skilful surgeon, the aneurismal tumor still remaining, although the femoral artery was tied above the aneurism. In this case the disease is no doubt seated in the profunda.

Many surgical writers and teachers have insisted on the doctrine, that when the aneurism is situated in the thigh, the ligature must always be applied to the profunda, lest the circulation of the limb should suffer. A distinguished surgeon of Philadelphia, performed opening the use of a femoral aneurism, and applying his ligature below the profunda, rather than carrying the artery higher up. The operation failed, however, and the patient still perished. That such facts are solely precedents, may be confidently asserted from analogy, furnished us we are with the knowledge that the aneurism, the common iliac, and even the aorta itself, may be obliterated, and yet the aneurismal vessels continue the circulation. But Dr. Wainwright, an accomplished surgeon of Charleston, S.C., has afforded a demonstration in a case of aneurism in the thigh, from a gunshot wound, in which he tied the femoral artery just below Poppert's ligament, and of course above the point at which the profunda goes off. The case has been completely successful, and the patient recovered without any morbid disposition in the circulation, and without any unusual symptoms.

The cases in which the femoral artery divides high up, which Professor Goussier has shown are by no means infrequent, may account for the successful failures of this operation, and should not be lost sight of by the judicious surgeon. As a general rule, however, applicable to all other cases, when the aneurism is situated immediately below the profunda, and in the vicinity of the profunda it is safer, and less laborious, to apply the ligature above. The action of the profunda may counteract the action of the operation, and the most powerful support may sometimes sustain the seat of the disease.—*Revue*.

There are other cases which might be quoted, but I shall simply state the efficacy of the aneurismal operation in the support of the limb, though the femoral artery had been tied, or obliterated in a very high situation.

Besides these facts, surgeons derived every encouragement to attempt the cure of popliteal aneurism, by the ligation of the artery above the cancer, from the elucidations given by Winslow and Hunter concerning the anastomosing communications which exist between the upper and lower articular arteries. Hunter even drew the conclusion, that if the course of the blood were interrupted in the popliteal artery, between the origin of the two orders of articular branches, such aneurism would suffice for carrying on the circulation in the leg. And at length Rivière, weighing the anatomical observations of Winslow and Hunter, and the facts recorded by Borelman and Rivière, first proposed applying to popliteal aneurisms an operation, which, with the exception of these two cases, and until this time been restricted chiefly to aneurisms of the brachial artery. (*Ann. de Chirurgie, Structures Anesthésiques*, 1799, *Chim. Paris* 1799, 1800.)

It was in Italy that the earliest operations were undertaken for the cure of popliteal aneurism, by Graaf, but, or rather by a German surgeon named Keyser, as would appear from a letter written by Tom to Omerig. (*Ann. de Chirurgie, Structures Anesthésiques*, 1799, 1800.) The success obtained by these surgeons soon led others to imitate them, and by degrees, the practice of tying the femoral artery became common both in cases of aneurism and wounds; and from the observations of Winslow (*Med. Disp.* 1799, 1800), Arvid (*Annales de Chirurgie, Structures Anesthésiques*, 1799, 1800), Loder (*Ann. de Chirurgie, Structures Anesthésiques*, 1799, 1800), Borelman (*Ann. de Chirurgie, Structures Anesthésiques*, 1799, 1800), and many others, it was proved beyond the shadow of a doubt, that the circulation might continue in the limb after the obliteration of the femoral artery, whether such obliteration were effected by direct pressure of the ligature.

The exact period when the first operation of tying upon the femoral and tying the profunda artery was performed in England, is not, as far as I know, particularly specified. However, judging from the allusions made on this practice in the writings of Pott

(Remarks on Palsy, &c. See Lond. 1779), of Wilson (Cancer and Aneurism in Surgery, See Lond. 1779), of Kirkland (Thoughts on Aneurism, See Lond. 1780), and of others, it is clear that this method of treatment had been often done in this country earlier than the date of those works, and as would appear with little or no success. The earliest instance of this kind in France was made by Cuyper in 1781 (*Ann. Chir. Chirurg. de M. d. l'opérateur*, t. 1, p. 555), about five-and-twenty years after the examples set by Guastaldi in Italy; but Cuyper failed in his endeavours to press the blood from the exposed cavity of the tumour, and was therefore obliged to amputate the limb. Subsequently to this attempt, the operation was undertaken by Velpeau in two instances, the terminations of which were successful. Consequently, this method may be regarded as entered to the honour of having proved to his contrivance the possibility of entering the popliteal aneurism, by laying open the sacculus, and securing the artery in the limb.

The severity and danger in all instances of this method of operating I have already noticed, and shall repeat the objections to it. With respect to the hæmorrhagic pressure, the great venousness of which were thus the artery in some distance above the tumour, and not opening the swelling at all, Hæmorrhoids were excited that Hunter's artery should be altered in its position, which he conceived was in reality the intention of Guastaldi. Here we observe, that again pain is a poor claim, and with respect to the latter, because the method of which he speaks only resembled Mr. Hunter's, inasmuch as it was not as directed to be tied at some distance above the swelling, while Guastaldi only tied the artery close above the tumour, and opened the swelling, a serious deviation from the Hunterian practice.

Guastaldi, a disciple of Ambrose Pare, having to treat an aneurism at the bend of the arm, the compression of bandages, exposed the artery above the aneurism, and five vessels then opened the sac, took out the coagulated blood, and dressed the wound, which healed by suppuration. After more than a century, And, as being consulted about a similar case, tied the artery above the swelling, which was left to itself. The patient recovered, the hæmorrhage became smaller, and healed, and left some marks as traces of the disease were perceptible.

In 1785, Desault operated in the same manner for a popliteal aneurism: the swelling diminished by manual and the bloodings raised; on the fifth day it burst, coagulated blood and pus were discharged in large quantities, and the wound, after continuing a long time fistulous, at length healed. Towards the end of the same year, says Faguet, Desault applied the ligature somewhat differently: instead of placing it close to the swelling, or directly above it, he put it on the inferior part of the femoral artery. (*See Nouveau Chir.* t. 4, p. 98, 99, 101, 5.)

Unquestionably, And did, in one solitary instance, tie the femoral artery immediately above an aneurism at the bend of the arm, and effected a cure without opening the swelling (*Journal de la Nouvelle Méthode de guérir les fistules indurées*, p. 231, Paris, 1710); but he did not think of applying the plan in the femoral artery, or draw the attention of French surgeons collectively to the matter, to make them imitate this operation: on the contrary, the method fell into disuse, and was never repeated. With regard to Desault's operation, said to have been done in an earlier part of 1785 than Mr. Hunter's first operation, it is only necessary to say, that Desault tied the popliteal artery itself, while the grand object in Mr. Hunter's method was to take up the femoral artery, at a distance from the disease, and that it is thus last mode alone which has gained such approbation, and been attended with successful success.

The French surgeons have not practised the Hunterian operation with the same degree of success with which it is now performed in England, and consequently they very commonly pursue the old method of entering the sac, &c. Even Boyer avers the insufficiency of what he calls Hunter's plan. (*Thèse de M. d. l'opérateur*, t. 9, p. 185.) But we shall not be surprised at their ill success, when we find that they reject the right principles on which ligature ought to be applied to aneurism, as explained by Mr. Jones in his work on hæmorrhage. Even Bland Regault adheres to the

use of ligatures of aneurism; and Boyer applies four iron ligatures round the artery, besides two tight ones; and consequently, a large portion of the vessel lies separated from its natural connection, and limited by these extraneous substances. Hunter's first operation nearly failed also on account of too many ligatures, some of which were tightened so as to cut through the true coats of the artery, and thus process to closure. (*See Hunter's Works*.) With reference to the operation of popliteal aneurism, Rosenkrantz's *Chir. Anat. Placida* deserves to be mentioned, Part 3, Tab. 2, c. 2. Scarpa's and Tiedemann's successful operations, and Haller's losses should likewise be examined.

ANNEALS OF THE LAW, 1809, FOREIGN, AND ELSE.

Books were not long ago entertained respecting the possibility of curing an aneurism at the upper part of the calf of the leg by tying the femoral artery in the middle of the thigh. (*Archives de Med. Sciences de Arts*, vol. 1, part 2, p. 363.) The author here referred to was led by this uncertainty to have recourse to one operation on the above method of laying open the tumour, in order to get at the vessel lower down. On this case, Scarpa makes some correct reflections: the apostolic judge has answered himself, that, in compressing the femoral artery at the upper part of the thigh, the femur of the leg of the patient is in contact; and that, when the compression was continued for some time, the swelling partly disappeared, and became softer. It ought to have been evident, therefore, that the aneurism might have been cured by tying the trunk of the femoral artery, as described in the foregoing section. In Scarpa's work is a case in which an aneurism in the bifurcation of the popliteal artery was cured by the ligature of the femoral artery. (*See p. 364, c. 3*.) Mr. Hodgson has seen three aneurisms situated at the commencement of the total aneurism, named by the same operation. (*On Aneurism of Arteries*, &c. p. 371.) But, as Scarpa remarks, though the Hunterian operation answers in the case of aneurism in the bend of the arm, and at the upper part of the calf of the leg, it is not so successful for aneurisms situated on the back or palm of the hand, or the dorsum or sole of the foot. The free communication which the ulnar and radial arteries keep up with each other in the hand, and the iliac arteries have in the foot, prevent the operation from succeeding whether the tracheal or femoral artery, or one of the two large arteries of the forearm or leg, be tied. In proof of this statement, Scarpa cites two cases of aneurism seen by himself; one at the instep, the other in the sole of the foot; and a third case of the same disease in the latter situation; all of which were found to be intrinsically the progress of the arteriovascular aneurism. (*P. 361*.) He thinks, however, that the operation of tying this vessel where it passes over the dorsum of the foot might succeed, if aided by compression, applied with a strap to stop the vessels through the other main channel; and he seems to approve of this practice, because the plan of tying the artery above and below the disease (which is the most certain mode of cure) could not be done, without extensive lacerations in the sole of the foot. In an aneurism at the lower part of the leg, Mr. Hodgson judiciously cautions against the practice of tying the artery, as best as possible in the tumour, because the constant circulation through the large interstices in the foot might with ease be swelling to aneurism, in consequence of the blood being driven out from the lower extremity of the vessel, forcing through the anastomosing artery branches, and so forth, the artery between the aneurism and the ligature. (*P. 363*.) Having in one case of aneurism of the arteriovascular artery, Mr. H. Clane applied a ligature just above the tumour without success, and Sir Astley Cooper expressly recommends making an incision in the skin, and applying a ligature both above and below the swelling. (*Lectures*, &c. vol. 2, p. 12.) When aneurism arises from the radial, ulnar, or interosseous arteries near the elbow, tying the tracheal vessel suffices; but if the disease be lower down, the vessel from which a prolepsis must be taken up over the swelling. (*Med. Ann.* p. 203.) A case, strikingly illustrative of this truth is recorded by Mr. Lawson. J. M. P., aged 19, applied to him on the 20th of July, on account of an aneurism at the left radial artery, about the middle of the forearm, discovered by a wound. The tumour was as large as a walnut, and so compressible, that it could

ality in placing the ligature above from the middle, not being sufficiently positive; but the further operations of the knot Mr. Addison very properly recommended the ligature to be put round the artery by means of an instrument resembling a catheter, the wire of which has a little size at its extremity, and can be pushed on and over beyond the end of the tube.

The patient went on tolerably well for some time after the operation; the pulse never exceeded 120, and after a few weeks to 90 or 80. He became exhausted, however, partly by the discharge, and partly by hæmorrhage, and died on the 21st of May, about fourteen days after the operation. It was discovered, on the day of the interment, in the situation of the aneurism, was completely filled with coagulated blood. "The ligature, on moving a part of this (though with a sponge, readily detached it, and without doubt had been disengaged for some days." The internal division, which appeared to have been tied, had separated about an inch and a half from the bifurcation with the external tie. By "supra" I conclude Mr. Addison means, that the upper part of the aneurism had been separated from the continuation of the artery vessel—(See *Medical and Phys. Journ.* vol. 25, p. 207, &c.) Although this gentleman has not given a very clear account of some part of his dissection, and he has also omitted to describe the place of his external incision, or the extent, parts which he divided in the operation, yet I think that all the circumstances of the case taken together leave not the slightest doubt of the external tie artery having been actually tied. The complete dissection of the pulsation as seen as the ligature was applied, and the testimony of several respectable anatomists will seem to prove, being indeed in general, as expected. The pulsation is seen referred to Mr. Addison for this important communication, which was in some degree repeated, it is true by Mr. Addison's master, but as it is well known that some distinguished mathematicians and surgeons in that university formerly expressed very strong doubts of the gradual nature of the operation.

The internal tie artery is also said to have been tied with success by an army surgeon in Russia, upon whom the late Emperor Alexander settled a pension as a reward for the skill displayed in the treatment of the case.—(See *British Medical Review*, p. 26.)

The external tie has also been tied in this country successfully for the cure of giant aneurism, by Professor White, the lecturer of Berkshire Med. Institution. This case is published in the second number of the *American Journal of Medical Sciences*, and is also referred to in Johnson's *Medical-Chirurgical Review* for April, 1828. It is the fourth instance in which it has been ever attempted; and three out of the four have been successful. The only time it was ever performed in Great Britain is the only instance of an Aneurism—*Notus*.

In a modern medicine are given a few particulars of a case, which was supposed to be an aneurism of the gastric artery, and cured by tying it precisely, a high vegetable diet, gentle laxatives, and digitalis.—(See *Trans. of the Philosoph. Soc. of the King's and Queen's College of Physicians in Ireland*, vol. 3, p. 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

Stanford has recorded an instance of an aneurism of the internal tie artery itself.—(See *Philosoph. Journ.* vol. 10, p. 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

The operation has been been tied in any case of aneurism of the external or internal tie; but Professor Cline has continued to use a ligature round it as an example of general success. "The patient died fifteen days after the operation, and then died from peritonitis, and from absorption of the artery. The aneurism in the ligature of aneurism tie was re-established about the second day after the artery was tied."—(See *American Med. Repository*, vol. 2, p. 165; and *Crichton's Treatise of Surgery*, vol. 2, p. 115, Philadelphia, 1825.)

(As an act of justice to my distinguished friend Professor Hall, I have been a detailed account of this successful operation, which Dr. Cline admits to have never before been performed. It is also honorable to him, as the profession, and to the country. It is introduced
Vol. I—1

cases, as communicated to me by the doctor at my side.

A detailed account of the first operation ever performed upon the external tie aneurism for the cure of aneurism, and especially of the first attempt to apply the ligature to so great a vessel, without dividing the peritoneum, may prove interesting to the profession generally, and must be immediately attributable to practitioners of surgery.

"On the 11th of March, 1827, I was requested to visit a patient with Dr. Osborn (of Westfield, New-Jersey, about twenty-two miles distant from New-York), whom Dr. Osborn, attending under a large number of the right external tie aneurism.

Israel Criss, aged thirty-three years, by occupation a farmer of Westfield and regular laborer, having generally enjoyed excellent health, says, about his middle of January he felt some pain about the lower part of the belly, which he attributed to a full stomach during the winter. He is, in some kind of more great efforts in lifting heavy logs of wood, as his employment at this season consists in carrying wood to market. He, however, was not until a fortnight since that he perceived any tumor about the lower part of the abdomen. Upon examination, the abdomen on the right side was considerably enlarged from about the crural arch, as high as the umbilicus. When the hand was applied to the parietal of the abdomen, a pulsation was felt and retained visible to some extent. To the touch the tumor was violently, and appeared to contain only fluid blood. It extended a little above Poupart's ligament, and reached halfway to the knee, from without near the navel, towards the middle of the side, upwards and backwards along up all the curvature of the stern, and reaching beyond the posterior axillary process of that bone.

The rapid increase of this abdominal tumor occasioned, as the consequence of our patient indicated, the most extreme agony. The sufferings of Criss were so great that his screams could be heard at a distance from the house. He had been bed several times, taken light food, and was kept constantly under the effect of opium. He was now informed of the serious nature of his case, and that without an operation very little chance of his life remained; with great composure he immediately consented to whatever would give him the best prospect of saving his life.

From the nature and situation of the tumor he was apprised of the uncertain nature of the operation, as well as the difficulty of performing it, and indeed that it would require an artery to be tied, which never had been before operated upon for aneurism. With these facts of the situation he cheerfully submitted to be placed upon a table of suitable height, in a room which was well lighted.

Then, in the presence of Dr. Osborn, Dr. Liddle, and Dr. Chase, the following operation was performed:—

The patient and groin of the right side being shaved, an incision was commenced just above the external abdominal ring, and carried in a semicircular direction half an inch above Poupart's ligament, until it terminated a little beyond the anterior axillary process of the ilium, making it in extent about five inches. The integuments and superficial fascia were now divided, which exposed the integuments part of the external oblique muscle; upon cutting which in the middle course of the patient, the muscular fibres of the internal oblique were exposed, the fibres of which were cautiously raised with the forceps and cut from the upper edge of Poupart's ligament. This exposed the spermatic cord, the cellular covering of which was now raised with the forceps, and divided to an extent sufficient to admit the long-thigh of the left hand to pass upon the cord into the internal abdominal ring. The finger moving now as a director, enabled me to divide the internal oblique and transverse muscles in the middle of the internal division, while it exposed the peritoneum. In the division of the first-mentioned muscle upwards, the incision of artery was cut through, and it yielded for a few minutes a smart bleeding. Thus, with a smaller artery upon the surface of the internal oblique muscle between the veins, and one in the integuments were all that required ligature.

With the internal beating of Poupart's aneurism, I now attempted to raise the peritoneum from it, which we found difficult and dangerous, as it was adherent to it in every direction. By degrees we separated it with

Professor Hulse has lately died the victim of one in a child less than two months old but a suppurated aneurism of one of the ilia. She recovered from the operation, but perished a few weeks afterwards from absorption of the aneurism.—*Ibid.*

ANEURISM OF THE BRACHIAL ARTERY.

Surgical writers mention many instances of aneurism at the bend of the arm, produced by the pressure of the brachial artery in passing over, or injured by a blow violent inflicted at the bend of the arm, or at the inner side of the humerus, or on the axilla. Such cases must indubitably be formed by effusion. Although Morgagni and others have stated, that, done with attention, aneurism caused by a wound of the brachial artery, the diameter of the vessel is sometimes unusually enlarged through its whole length above the seat of the lesion, this enlargement, which is very rare, might have occurred naturally before the rupture occurred. Even were it so, it would not explain the formation of the aneurism, and at the bend of the arm, along the inner side of the humerus, or in the axilla, after wounds.—(*Saunders*, p. 168.)

The pressure caused in these cases may certainly be caused by the aneurism of continuity in the two proper parts of the artery, and the consequent effusion of blood into the cellular substance. The effect is the same, whether from an internal ruptured aneurism, capable of absorbing the humerus and the bones of the arm, the blood be effused into the neighbouring cellular sheath surrounding the artery, which it raises after the rupture of an aneurism, or on the wound of the aneurism having closed, the blood be so forced into the artery, and be effused in the surrounding parts. The arterial substance on the outside of the wounded vessel is first injured, as in an aneurism; the blood then distends it, and the vessel is in the form of a tumour, and the cellular substance being destroyed, continues, as at first, a firm capsule of aneurismal sac.—(*Saunders*, p. 171.)

The precontracted or the dilated state of the aneurism, and the regular or irregularity of its formation, depend on the greater or less resistance to the impact of the blood, during the time of its effusion, by the aneurism of the cellular substance surrounding the artery, and by the ligaments flexor and supinator, lying over the sac. The aneurism of the brachial artery being only half as long broad, and situated lower than the common place for bleeding, cannot, at least in such cases, indubitably absorb the cellular substance surrounding the artery, as is commonly supposed.—(*Saunders*, p. 168—171.) This author recovers the greatest resistance for the aneurismal ligaments, which, after having covered the body of the brachial muscle, extends over the whole course of the brachial artery, and is impregnated into the arterial coat. This ligamentous expansion has a triangular shape, the base of which extends from the tendon of the biceps to the internal condyle, while the apex reaches upwards along the inner side of the humerus towards the axilla, in the course of the artery. The brachial artery and median nerve, kept in their situation by the cellular sheath and the ligamentous expansion, run in the furrow formed between it and the internal margin of the biceps.—(*Saunders*, p. 171.) This author authoritatively explains many aneurisms relative to the different, aneurismal, shape, &c. of brachial aneurisms by this aneurismal ligament. While aneurisms, from an internal cause, are not infrequent in the axilla, thigh, and hand, they are very rare in the brachial artery, though a few such instances are recorded.—(*Saunders*, p. 170. *Fallopia*, *Chirurgia*, lib. 2, p. 4.)

The mode of aneurisming a wound of the brachial artery in attempting to bleed, and the method of trying, in efforts made by pressure are described in the article *Hæmorrhage*.

And was the first who tied the brachial artery for the cure of the aneurism at the bend of the arm, to the name may this Hulse did the honour for the cure of aneurism in the ilia, viz. was one who placed above the aneurism, without making any incision, spot or tear the sac itself.

The operation is performed as follows:—The surgeon, having traced the course of the brachial artery, and felt its pulsations above the aneurism, he may either cut down on the vessel transverfly above the tumour,

or make higher in the long suture between the origins of the superior and inferior collateral arteries. The aneurismal sac is to be divided in the centre of the artery, and also the cellular sheath for the space of about two inches and a half. The surgeon, now introducing his left fore-finger to the bottom of the wound, will feel the distended vessel, and if it is not sufficiently bare, he must divide the parts which will cover it, observing to divide the edge of the knife on the side next to the internal margin of the biceps, to avoid dividing any of the numerous structural branches which go off from the opposite side of the artery. He is then to separate with the point of his finger the trunk of the vessel, above a line, or, if together with the median nerve and vein, and expose it a little from the bottom of the wound. He is to separate the median nerve and vein far a small space from the artery, and with an eyed needle is to pass a ligature under the latter, and then tie it with a single knot.

In the operation it should always be recollected that the median nerve lies on the inside of the artery, and, therefore, that the instrument used for pulling the ligature under the vessel should be passed from within outwards, by which means the instrument of the nerve may be more easily avoided.—(*Boyer*, *Traité de Médecine Chirurgicale*, &c. t. 5, p. 193.)

The operation is well described by Mr. Hodgson:—“The surgeon divides the integuments along the inner margin of the biceps muscle by an incision two inches and a half in length. The thin fascia which surrounds the arm will then be exposed, and must be carefully divided in the direction of the external wound. The artery lies immediately under the fascia close to the margin of the biceps. The median nerve is situated on the inner side of the artery which lies between its two true courses. The internal cutaneous nerve is also exposed under the fascia in the middle of the arm, and lies on the same side as the median nerve. The cellular membrane which covers these parts is to be divided, with the care of the artery are fully exposed. This part of the operation will be effected with facility, if an assistant compress the artery above the wound, so as to stop the circulation through it, and render it in some degree dead. The point of an aneurismal needle is then to be introduced close to the skin, and brought out on the radial side of the artery, so as to avoid including the median nerve, or the vein which accompany the artery.”—(*On Diseases of the Arteries*, &c. p. 263.)

Whenever, after the above directions, says Saunders, shall have the treatment of a circumscribed aneurism in the bend of the arm well so taught, it is to be noted, follow the method of those who, supposing the tumour to be formed by the dilatation of the artery, used first to divide the integuments over the tumour, incised the sac, and sought for the vessel above and below the aneurism, in order to tie it in two places; and then endeavoured to make the sac absorb itself. The operation is now reduced to the greatest simplicity, viz. tying the artery merely above the tumour.—(*See Saunders*, p. 266, 268.)

When the aneurism is diffuse and accompanied with violent inflammation and swelling of the whole arm, from the excessive dilatation of the vessels effused blood, Saunders recommends the old operation of opening the tumour, and tying the artery at the bottom of the sac above and below the vessel made by the latter. In this method a tourniquet must be applied to the upper part of the arm, near the axilla, or, if the limb be very painful and swollen, it is better to let an assistant compress the artery from above the elbow, against the first rib. The incision having been made into the tumour, and the blood discharged, a probe is to be introduced into the pulsation in the vessel, from below upwards, as far as reach the artery. This, being separated from the parts beneath, and the median nerve, for a small extent, is to have two ligatures tied under it, one of which is to be tied above, the other below, the second in the vessel. Then the tourniquet, or pressure, is to be taken off, and if there be no bleeding, the vessel is to be made to bleed. —(*See Saunders*, p. 268.) With reference to this operation, Boerhaave (*Clar. Anat. Medica*, lib. 9, tab. 11, *Scutula* plures, *Tendons* &c.) has said, in his description of the arteries, and Campbell (*Præceptor. Anat. Patol.* lib. 1. art. 100) commenting.

It was on the brachial artery, that Mr. Lander

(Med. Obs. and Inquiries, vol. 3) details the experiment of closing the pulsation in the vessel by means of the twisted string, under an anæsthetic, and the plan would not, like compression, obstruct the arterial tube, and therefore that the risk of gangrene would be lessened. Now, although in the trial which was made the bleeding was completely stopped, Lambert was mistaken in supposing that the temporary closure of the weakened part of the artery was lessened by the adoption of the twisted string, instead of pressure on the ligature. If ever a small pressure is so easily lost, so as to leave the tube of the vessel pervious, it is under the circumstances pointed out by Mr. Jones.—(See *British Med. J.*) Had Lambert had an opportunity of observing the state of the vessel some 1000 days after the above operation, he would have found its canal unobstructed; and had he known the freedom with which the collected arteries anastomose with the nearest arteries of the limbs, he would have known how to explain, more correctly the re-establishment of the pulse. I need hardly add, that as the false idea of preserving the perviousness of the artery was the only foundation for the treatment, the patient could never be cured, as no affecting equal severity from ligatures to that obtained by the ligature, is even conceivable.

STILLBORN EYESIGHTS.

Aneurisms occasionally take place in the aorta, and make it necessary to tie the subclavian artery. A question here naturally presenting itself is, whether the surgeon should attempt the operation in an early period of the disease, or wait till circumstances are urgent; the aneurism large and far advanced; the arm obstructed and thus perfectly paralysed, from the interference of the rapidly growing vessels; the patient worn out by suffering and loss of rest; and the danger in danger of bursting? In all cases of aneurisms, unquestionably, there is a certain chance of the disease getting well spontaneously; and in military aneurisms, as is seen in St. Bartholomew's Hospital a few years ago, had seriously disappeared of itself, or was cured by the accident when the patient while lying gave off his case, and by the obliteration of the artery, found no improvement after death.

I believe, however, we ought not to suffer our conduct to be too much influenced by the hope of an infrequent cure, and, from the observations which I have made on this subject, it is my decided opinion, that the operation should never be delayed, so as to allow the patient to acquire an insupportable state. The operation is always difficult; but the difficulty is very easily increased, when the swelling has extended far towards the breast, and has become so large as to push the clavicle considerably upwards. The second example in which the subclavian artery has ever been successfully tied I have observed, proved that the aneurism was fully competent to the supply of the limb with blood. The plan, therefore, of delaying the operation long, with the view of allowing the communicating arteries to enlarge, must be as questionable here as in some other cases of aneurisms; and at all events, the same may be safely advanced, that, previously to the operation, the patient should never be allowed to acquire insupportable pain.

That the limb would receive an adequate supply of blood was well proved, even without the performance of the operation, by cases in which the axillary and subclavian arteries had been checked separately by Douville, as, for instance, by the pressure of an aneurism of the arm.—[For an account of such facts, the reader is particularly referred to *Observations Pratiques sur le Raccourci de l'Arterie*, p. 111; *Journal de Médecine de Chirurgie de l'École de Paris*, t. 2, p. 22; *Consult. Paris*, par M. Blandin de l'École de Paris, p. 218.]

"In this case," says Mr. Hodgson, "the only reason why success which was observed during the operation was due to the deficiency of the pulse at the time the patient was tied, and not to the fact of the vessel being tied." The axillary artery (the subclavian) was obliterated a few days after it had given off any branches."—(P. 67.)

This case was tried by Mr. Hall, at Chelsea, when it had been wounded with a syringe, and an aneurism formed; the arm was preserved, though it remained somewhat swollen, which might be owing to the division of anastomosing vessels. (*Med. Hall on Wounds*, p. 19, vol. 1, and *Scrup.*, p. 277.) Mr. White, at Man-

chester, relates another instance of this vessel being tied, in the case of a wound, but mentions of the limb and limb followed. Three of the nerves were tied and included in the ligature.—(*Lancet*, Med. Journ. v. 1, 1840, p. 100.) In cases of wounds of the axillary, or any other large arteries of the extremities, the surgeon, before proceeding to apply a ligature, should first ascertain the precise point of the wound in the artery; and for this purpose, it may sometimes be proper to cut the middle of the shoulder, to make an incision in the muscle so as to expose the injured part of the vessel; or, if circumstances do not forbid, the external wound may be dilated, until the exact part where the artery has been wounded is discovered. In proof of the propriety of acting in this manner, and applying a ligature above and below the wound in the vessel, Scarpa gives a case, in which such practice was successful in a patient under M. Maunoir, of Geneva: the artery had been injured with a sabre near the head of the humerus; but after the wounded part of the vessel had been traced, and secured in the way above suggested, the patient, a boy thirteen years of age, was cured from the dangers of hæmorrhage, and restored the use of his arm, so that as this was possible, with the loss of the first phalanges of the last three fingers from gangrene.—(See *Scrup.* on Aneurism, p. 412, v. 2, and *Journ. de M. d. 2, 3, 4, 5, 1817.*)

There are two modes of operating for axillary aneurisms, viz. by cutting below the clavicle, in order to take up the axillary artery itself; the other, by making the wound above the bone, for the purpose of securing the subclavian artery at the point where it emerges from behind the anterior scalene muscle.

The first of these methods has been attempted by Douville, Pottier, the late Mr. Keen, Mr. Chandler, &c. It was in a case of wound of the axillary artery that Douville operated. An aneurism, six weeks long, was made below the external third of the clavicle; two thoracic arteries cut were transversed; and the two lower thirds of the great pectoral muscle were cut dividing with a temporary groove on a director; a large quantity of coagulated blood was now discharged; and the artery was directly taken hold of, and tied together with the brachial plexus of the nerve. The arm remained, and the patient died. This case, we must agree with Scarpa, was not a fair trial of the operation, inasmuch as the inclusion of the plexus of nerves in the ligature was an improper measure, and must have produced the occurrence of aneurism. It seems also probably, from the account, that the vein was likewise tied; another serious and important proceeding. Besides, it is worthy of notice, that the case was a wound of the axillary artery, attended with a copious effusion of blood in the cellular membrane in the muscles of this kind, gangrene is necessarily induced, than when the case is a more circumscribed aneurismal tumour.—(See *Chirurg. Clin.*, de Douville, par Fothergill, t. 2, p. 253.) As for Pottier's attempt, it hardly deserves notice, because the operation did not even succeed. His colleague opposed to dividing the pectoral muscle; a rupture, therefore, was made with a needle and ligature; but the artery was not touched, and the operation was not repeated.—(See *Chirurg. Clin.*, t. 2, vol. 1, p. 44.)

In a case of axillary aneurism, which had already burst, and the hæmorrhage from which could only be stopped by pressing the artery against the first rib, Mr. Keen, the surgeon-general, practised the following operation, which was attended with complete success. His plan was to take up the artery above the wound and captured part, in its passage over the first rib. Accordingly he made an incision obliquely downwards, divided the fibres of the pectoral muscle that were in his way, and, when he came to the artery, passed a curved, sharp-pointed silver needle, armed with a seton, under the artery, and tied one of the ends. After a careful examination, finding that the artery passed below the ligature, he determined on passing another ligature higher up, and inserted at the clavicle, he, therefore, passed the needle more deeply, so as evidently to include the artery. In a few days the swelling of the arm began to subside, the wound suppurated, and the ligatures came away with the dressing. The arm afterwards recovered its freedom; and the patient remained in a good humour, the entire removal of the aneurism, &c.—(*The Med. Review and Magazine for 1843*.)

Mr. Keate's operation is shortensided, transverse, as it was a fine guide with a needle, and attended with great danger of wounding and tying parts which should be left unincised.

Mr. R. Chamberlaine, of Huggins, Jamaica, took up the aortic artery below the diaphragm, in a patient who had an aneurism in the left axilla, communicated by a vessel with a cutaneus in the 10th of October, 1818. On the 16th of January, the tumor had considerably increased, but was less compressible than it had been when first seen by Mr. Chamberlaine. The operation was done on the 17th of January, 1819. "A transverse incision, of three inches in length, was made through the skin and pterygoid muscles, along and upon the lower edge of the clavicle, three finger's breadth from the sternal end of that bone, and terminating about an inch from the transverse scapulae. This incision divided a small artery, which was immediately ligated. A second incision, of three inches in length, was also made obliquely through the integuments over the deltoid and pectoral muscles, ending the first nearly in the centre. The pterygoid muscles and all lying between them at the upper part were now removed. The next step consisted in detaching the clavicular portion of the pectoralis major, and taking away the fat and cellular membrane lying over the subclavian vessels. The artery was now brought into view, and its pulsations made it clearly distinguishable from the contiguous veins." After several ineffectual efforts, Mr. Chamberlaine succeeded in passing a ligature under it, by means of an eye-needle, curved for the purpose, and the point of which was brought up with the aid of a pair of forceps. On the 22d of February, the wound was completely healed; the aneurismal tumor reduced to the size of a turkey's egg, and very soft; the arm smaller than before, but its muscular power improving.—(*See Medical-Cur. Trans. vol. 1, p. 226, &c.*) Mr. Chamberlaine expresses his conviction, that the operation would have been much facilitated, had he been furnished with the instrument described in Mr. Harwood's work for passing the ligature under the artery; a still better invention, however, he presents a ligature under a deep artery, in the neck, lately constructed by Mr. Weiss, surgeon's instrument maker, in the Strand. An engraving and description of this portable instrument may be found in the *Med. Mag. and Surgical Journal*, No. 16.

The subclavian artery might be cut at below the clavicle as follows: the surgeon is to begin at incision in the integuments about an inch from the sternal end of the bone. The cut is to run towards the axilla, avoiding a little downwards from a line parallel to that of the clavicle. This wound will bring into view some fibres of the great pectoral muscle originating from the 5th rib-costal bone. These are next to be divided down cellular substance will be found underneath, which is to be carefully raised with a pair of dissecting forceps, and cut. The operator will then arrive at the great subclavian vein, and separate vein arising with it. Under the subclavian vein, and a little further backwards, more under the clavicle, the subclavian artery may be seen and tied.—(*See C. Bell's Operative Surgery, vol. 2, p. 273.*)

On the whole, however, I think, Mr. Harwood's directions for the performance of this operation are the best which have been given. A transverse incision through the integuments, which is to have an obliquity downwards, and to begin about an inch from the sternal end of the clavicle, being continued towards the axilla for the intended three or four or less, as is to end near the axillary margin of the deltoid muscle, without reaching any connection between the deltoid and pectoral tendons, after it would remaining the epigland vein. This incision will expose the fibres of the pectoralis major, which are next to be divided to the dissection and extent of the external vessels. The flap is then to be raised by dividing the lower cellular membrane which connects the pectoral muscle to the pectoral aneurism. The pectoralis minor will also be seen crossing the inferior part of the wound, and, by retracting the flap between the upper edge of the pectoralis major muscle, the surgeon may see the pulsations of the aortic artery. Here one of the several curves lies down, lying in contact with the artery; the other curves lie behind it. In the third arch, the artery was in contact below it; but, on the living, the vein is divided, and above the artery. The cellular membrane transposing these parts into is

separated by careful dissection, or by lacerating it with a sharp aneurism. A ligature having been drawn under the artery with an aneurism-needle, the ends of the cord are to be brought, and a large twisted suture, so as to compress the part over which the ligature. If the artery is incised, the pulsations in the aneurism will immediately cease. This procedure is highly necessary, but one of the cervical nerves should be tied, instead of the artery.—(*See Harwood on Diseases of Arteries, &c. p. 282.*)

When an aneurism extends a certain way towards, or towards the trachea, the incision below the clavicle becomes impracticable, and it is now requisite to make the incision above that bone, and take up the subclavian artery at the point where it comes out from between the vertebrae and lies in the for space of the 6th rib.

In the above subject without any incision under the clavicle, this operation is easy enough; but in a third patient the difficulty is much increased by a large cellular aneurism, for then the clavicle is sometimes as much elevated, and the artery lies so deeply, that a ligature can hardly be carried under it without a puncturing needle by the process. This was the case in an aneurism which I once saw made by Mr. Harwood to tie the artery, and in which one of the cervical nerves suffered by the pulsation of the artery was mistaken for it and tied, so that the aneurism was afterwards burst, and a fatal hemorrhage arose. Hence the advice given by my friend Mr. Hodgson, always to operate in this case while the tumor is small, cannot be too well remembered. A direction given by Mr. Liston is also important, namely, "before tightening the ligature, try the effect of compression with the fingers on the pulsation, so by taking this precaution (says Mr. Liston) I saved myself and my patient the pain of tying the nerve, which got hold of in my first operation, in place of the artery."—(*Journal, No. 152, p. 224.*) The chief difficulty in the operation is that of passing the ligature round the artery, but it may be done either with an aneurism needle which Mr. Harwood has described, and which is exactly similar in principle to Desault's capsule & round, or with the still portable instrument constructed by Weiss. Another very ingenious contrivance by tying deep arteries has also been recently proposed by Dr. Thomas of Geneva.—(*See Edin. Med. and Surgical Review, No. 73.*) The instrument used by Dr. Nott when he took up the artery in aneurism was by presenty noticed.

In order to avoid the inconvenience of the needles ordinarily used for conveying ligatures under deep arteries, Desault (says Knight) invents "true ligature & retractor" composed of a silver tube or sheath, which was brought at one end and bent at the other into semicircular form. The sheath enclosed an elastic wire, the springing extremity of which was accurately fitted to the end of the sheath, and performed with a transverse eye. The instrument was passed under the artery, and as soon as it had reached the other side of the vessel, the sheath was kept fixed, while an assistant pushed the elastic wire, which, rising from the bottom of the wound, penetrated the aperture of the artery in the sheath, and then passed the ligature through this opening. The wire was next drawn back into the sheath again, and the whole instrument brought back beyond the artery, by which means the ligature was conveyed under the vessel.—(*See Quercet's Op. de Desault, par Mead, &c. 2, p. 264.*) Another very ingenious method of passing the ligature under the artery, is that practised by Mr. Key; but as the compression of it is difficult without the plate, I shall here merely refer to that gentleman's description of it.—(*See Med. Chir. Trans. vol. 12, p. 16.*)

The location of the foregoing instruments makes a general direction in the difficulty of taking up the subclavian artery from above the clavicle; but one is to be considered, that without such assistance, the operation should have failed even so as if it were aneurism, as Mr. A. Cooper.—(*See Gen. Med. & Surgery, vol. 2, p. 226.*)

The following example is the 5th in which the attempt to tie the subclavian artery by cutting above the clavicle was ever accomplished.

John Towry, a tinner, aged thirty-two, admitted to extensive dissection, of an aneurism and generally extensive corrosion, was admitted into St. Bartholomew's Hospital on Tuesday, the 25 of November, 1809, as a patient of an aneurism in the right axilla. The

protruded part of the tumour in the neck was about half an inch in diameter, and there was also much enlargement and distension underneath the posterior margin, so that the artery could not be brought near the side of the body.

"The temperature, at both times," says Mr. Harshden, "was 104°, and the pulse in the radial artery of each arm was correspondingly. After the patient had been put to bed, some blood taken from the left arm, and few hours elapsed, his pulse, which on his admission had been 120, became less frequent; his countenance appeared more tranquil; and he experienced some relaxation of the distending sensation in the affected arm; his mind, however, was in great darkness."

The incision of the radial artery of the affected arm, naturally became more extensive, and soon after another wound was made in the cubital artery of the left arm and hand. On the evening of the twelfth day, a dark spot appeared on the centre of the nape, surrounded by inflammation, which terminated in more extensive dissection of the skin. A further incision of the operation being deemed inadvisable, Mr. Harshden performed it the next day in the following manner.

"A transverse incision was made through the skin and platysma myoides, along and upon the upper edge of the clavicle, about two inches and a half in length, beginning at its insertion in the shoulder, and terminating its outer extremity at about half an inch beyond the external edge of the sternocleidomastoid muscle. This incision divided a small superficial artery, which was directly secured. The skin along the clavicle being then pushed up between my own fingers and finger and those of an assistant, I divided it both within outwards and upwards, in the line of the external edge of the sternocleidomastoid muscle to the extent of two inches."

"My object in striking in the skin for the second incision, was to expose at once the superficial veins, and by drawing them carefully from the external vessels, to place myself at my work without wounding them. This provision proved to be useful, for it rendered the flow of blood during the operation very trifling, comparatively with what might otherwise have been expected; and Harroby assisted me with the greatest facility in turning into view those parts which were to direct me in the artery."

"My assistant having now lowered the shoulder, for the purpose of placing the first incision above the clavicle (which I had designedly made along and upon that bone), I continued the incision, with my scalpel, until I had distinctly brought into view the edge of the anterior scalene muscle, immediately below the arch which is formed by the transverse belly of the obohyoides and the edge of the sternocleidomastoid muscle; and having placed my finger on the artery at the point where it presents itself between the scalenæ, I found no difficulty in tracing it, without touching any of the nerves, to the lateral edge of the upper rib, at which point I divided it with my finger nail, for the purpose of applying the ligature."

Here, however, some an embarrassment which (although I was not prepared for it) greatly retarded my expectations. I had intended, from repeatedly performing this operation many years since, on the dead subject, that to pass the ligature under the subclavian artery, with the needle, necessarily need no exertions would be superfluous; I had, therefore, provided myself with instruments of various forms and curvatures to meet the difficulty, each of which most readily conveyed the ligature underneath the artery, but would serve no farther; for being made of solid materials and thus inflexible, they would not allow of their points being brought up again at the very spot requisite, which the extensibility of the space between the rib and the clavicle afforded, and which, in this particular case, was rendered of natural utility by the previous distention of the vessels by the tumour."

After trying various means to overcome this difficulty, a probe of double round steel at length enabled me, which I passed under the artery, and bringing up its point with a pair of small forceps, I succeeded in passing on the ligature, and then tied the subclavian artery at the part where I had previously detached it for that purpose. The opening of the knee was attended with pain; the wound was closed by the dry matter, and the patient was then returned to his bed."

—See *Practical Observations on the Stomach*, &c., &c.

which are added four hours of operations for aneurism, p. 278, &c.]

"It only seems necessary for me to add, that immediately after the operation the passages of the swelling ceased; that the arm of the same side continued to be freely supplied with blood, and was even rather warmer than the opposite arm; that the operation, which was severe from the length of time it took up, was after a time followed by considerable indolence; that the patient died about five days after its performance; that after the artery had been tied, the activity of the arm and the aneurismal tumour partly subsided; and that, on examination after death, nothing but the vessel was found enlarged in the ligature."

In this particular case, descriptions of the tumour, which will be of great service to my fellow-practitioner of this operation. The description is a remarkable one, and which I have already endeavoured to give an analysis of. It is worthy of this instrument, I conceive, that the great utility of the operation will in future be proved. Had Mr. Harshden had his assistance, his patient would have been detained a very little time in the operating theatre, and the extent of the case might have been completely successful. Having witnessed all the circumstances of this case, the interest that I drew from them was, that if the operation could have been made in a moderate time, which now seems practically out of the aid of the surgical resource, the contrast will be by Mr. Wilson, the value is all probability would have ended well. The preceding case is particularly instructive, as being the first instance in which the subclavian artery was successfully tied, without any sudden thrust of a needle, and without the assistance of any part besides the artery in the ligature. It furnished encouragement to repeat the experiment; and all the hope, that activity assistance might be used as well as manual ones, and considered the impossibility of the aneurismal arteries to restrain the whole upper extremity, when the subclavian is tied where it emerges from behind the anterior scalene muscle."

In the year 1811, the subclavian artery was tied in the London Hospital, in a case of aneurism, by Sir W. Blizard, who found no difficulty in going the ligature under the artery, with a common aneurismal needle. A stable ligature was applied. At first hopes of recovery were entertained; but the patient, who was old and debilitated, afterwards sunk and died in the fourth day. —See *Blizard's Reports*, p. 373.

In the year 1815, Mr. Thomas Harroby tied the subclavian artery in the same hospital. The case was as singular in the left axilla, and like all the other examples of this kind upon record, was attended with great pain in the tumour and limb. There was no pulse in the left radial artery, though there was scarcely any difference in the temperature of both arms. An incision about three inches in length was made through the integuments at the end of the neck in the second rib, and parallel with the external jugular vein. The platysma myoides being divided, the cellular membrane was separated with the finger, and the pulsation of the subclavian artery was felt where the vessel passes over the first rib. The finger being pressed upon this part of the artery, the cellular sheath opening it was carefully opened with the point of a knife. A ligature was then introduced underneath the artery, by means of a common aneurismal needle, with the greatest facility. As soon as the ligature was tied, the pulsation in the tumour ceased. On the second day after the operation the left arm began to move more freely, and was as warm as the right. However, difficulty of breathing, twitches, delirium, &c. afterwards ensued, and the patient died on the evening of the eighth day, previously to which great thirst and multiple fingers started up. On opening the body, the practitioners exhibited the effects of a high degree of inflammation, and the heart was covered with a deposit of lymph, its posterior surface being of a deep red colour. The most remarkable of the aneurismal work was of a bright scarlet line, which clung, and was covered with white patches. A ribbon of yellow was also noticed in the lining of the right ventricle, left auricle, and even the whole of the system. The boundaries of the aneurismal tumour were in a state of consolidation. These are all the circumstances which I must here to notice, but more particularly may be perused in Mr. Hodgson's work, p. 602.

It is remarkable that in the cases operated upon in the Guy's Hospital, and some others on record, no difficulty was experienced in passing the ligature near the artery with a common aneurismal needle; a circumstance which might have depended upon the space between the glands and the first rib having been less deep in these instances than the two which fell under our own observation, or it may be which occurred in the practice of Dr. Colles, the Astley Cooper, and Mr. Liston. (See *Lancet*, *Med. Review*, vol. 2, p. 267; *Brit. Med. Jour.* and *Trans. Journal*, January, 1858, No. 41.) In Mr. Key's case, "the depth of the arsis is what the artery was considered to be; it was possible to pass a ligature under it, about three-quarters of an inch of the clavicular portion of the sternocleidomastoid was divided, which afforded sufficient room, and rendered the operating part of the operation easy; the artery became fully exposed in view, and its arterial venous trunk was secured with firmly under it." (*Med. Chir. Trans.* vol. 33, p. 22.)

In Dr. Colles's first case, the artery was tied before it reached the scalene muscles, as the ligature, which was in the high calcareous artery, extended from the medial angle of the sternocleidomastoid muscle along the clavicle, a little beyond the arch of that bone, and rose nearly two joints above it, in a curved form, the apex of the curve being situated at the inner edge of the diverging muscle. After a tedious dissection, it was found that only a portion of an inch of the artery was visible, and on this portion the ligature was placed. Great difficulty was encountered in passing it round the artery, and the artery was supposed to have been tightly wounded. Before touching the ligature the breathing became suspended, and the patient complained of oppression about the heart. These symptoms, indeed, were so violent, that it was judged prudent not immediately to tighten the ligature. On the fourth day, however, the artery was contracted, when the pulse at the wrist ceased, the patient not seeming to suffer much from what had been done. The patient then went on pretty well till the sixth day, when he was seized with a series of shivering and pain about his loins, and, becoming restless, died the hour after the beginning of this attack. On dissecting the artery was found divided, and the disease extended into the subclavian artery.

In another instance, Dr. Colles tied this vessel at the point where it emerges from between the scalene muscles, without any particular difficulty. The operation, however, was soon followed by a train of severe symptoms, delirium, and mortification, and the patient died on the fifth day. (See *Educ. Med. and Surg. Jour.* January, 1855.)

The first case in which complete success attended the operation of tying the subclavian artery, where it first comes below the sternocleidomastoid muscle, was that under the care of Dr. Post, of New-York. The patient was a gentleman, with no morbidities in the left arsis. Dr. Post performed the operation on the 8th of September, 1857, in the following manner. "An incision, commencing at the outer edge of the tendon of the trapezius muscle, was carried through the integuments about three inches in length, at a distance of about a line from a parallel line with the clavicle. This divided the external jugular vein, the bleeding from which required a ligature for its suppression; and in proceeding with the operation, three or four arterial branches were cut, which it was not necessary to secure. The subclavian artery was then sought immediately on the outside of the scalene trachealis and was found to be bare. Passing over the artery at this place, in contact with it, were three considerable branches of nerves, running downwards towards the chest from the plexus above. These were separated, and a ligature passed lightly over the artery with great facility by the instrument well adapted to this purpose invented by Drs. Parry, Harrison, and Hewson, of Philadelphia. On lifting the ligature, all pulsation ceased in the arm. It was observed, the temperature of the limb was increased to its former degree, that the arm was warm. On the 12th of September, the external carotid artery, and about three inches of the subclavian trunk were exposed. On the 15th, the trachea, after being tied to the subclavian artery. On the 17th, the second rib was removed, and on the 18th of the same month, the patient expired no farther advanced, his only complaint being now a little swell-

ing pain in the fingers, and a superficial abscess at the point where the ligature passed. (*Med. Chir. Trans.* vol. 3, p. 155, 60.)

Mr. Liston, of Edinburgh, has the honour of being the surgeon that first succeeded, in Europe, in tying the subclavian artery, by taking up the subclavian artery from above the clavicle, on the 30th of April, 1840. The particulars of the case are very interesting. They prove the risk there always is of tying one of the arterial vessels instead of the artery, unless great caution be employed; and, in fact, Mr. Liston himself first passed his ligature under a nerve, and would have tied it, had he not wisely tried to tie after passing the divided part round, have used the assistance of the finger. As the subclavian artery, instead of being at the point where it emerged from behind the superior scapula, Mr. Liston judiciously divided the muscle to reach its trunk, so as not to expose the phrenic nerve. Mr. Liston, with the aid of an aneurismal needle, he passed a strong needle with ligature under the artery, and having tied it, the lig. with 4 small knots withdrew the needle. In consequence of the great depth of the artery, the knot could not be made with the fingers; but with the assistance of a knot of bowline, each extremity of which had a little notch in it, the ligature was accomplished. (See *Educ. Med. and Surg. Jour.* No. 64.)

Several other successful operations of this kind have independently been done by Kistner, Simpson. One by Dr. Colles, in the General Naval Hospital of St. Peterburgh (see *Med. Chir. Trans.* vol. 32, p. 231); another by Mr. Bailey, in the Lyons Dispensary (see *London Med. Repository for Sept. 1857*); a third by Mr. Webster at Edinburgh (see *Educ. Med. and Surg. Jour.* No. 78); a fourth by Mr. Key, in St. John's Hospital (see *Med. Chir. Trans.* vol. 32, p. 1); and a fifth by Mr. B. Cooper, in the same establishment.

Professor Gibson, of the University of Pennsylvania, has made a case of aneurism anastomosing, by the junction of an old location of the aneurism, by tying the subclavian artery. (See *American Journal*, vol. 5, p. 185.) *Key.*

The instructions delivered by Mr. Hodgson for the performance of this operation, are the best with which I am acquainted. When the subclavian artery (says this gentleman) has emerged from behind the inferior scalene muscle, it passes obliquely over the flat surface of the first rib, with which it is in immediate contact. The external nerves are situated above and a little behind the artery; the subclavian vein passes before it, and undermost the clavicle. If the finger be passed down the external margin of the superior scapula muscle, the artery will be found in the angle formed by the origin of that muscle from the first rib. The shoulder being fixed down as much as possible, the skin is to be divided immediately above the clavicle, from the external margin of the clavicular portion of the trapezius muscle, to the margin of the clavicular insertion of the trapezius. No advantage is to be gained by raising the superior attachment of the infra-clavicular vessels. On this point, however, there is some difference of opinion. Mr. Key having found, in his operation, that the division of the clavicular portion of that muscle greatly facilitated the introduction of the ligature under the artery. (See *Med. Chir. Trans.* vol. 32, p. 5 and 61.) The exposed force of the patient's muscles are now to be carefully divided, without wounding the external jugular vein, which lies immediately lower down, near the middle of the incision, and should be detached, and drawn towards the shoulder with a strong hook. The cellular membrane, in the middle of the incision, is then to be cut, or separated with the finger, until the largest artery at the superior edge of the inferior scapula. He passes his finger down the margin of this muscle, until he reaches the part where it curves from the first rib, and in the angle formed by the origin of the muscle from the first rib, he ties the artery. The ligature is made to be carried under the vessel with an aneurismal needle, or that recommended by Hewson. (See *Med. Chir. Trans.* vol. 32, p. 334 and 5.)

Hodgson thinks that the apex and middle of the rib that supports the ligature. An incision, three or four inches long, is to be made at the lower and outer part of the neck, and extended to the clavicle. This first incision, exposed behind the external edge of the sternocleidomastoid muscle, should go through the skin,

eye of one of the above-described needles, and entered the needle into a bundle, he pressed with his index-finger the cellular membrane and plexus carefully downwards, while he turned it from below upwards toward the artery. As the point now appeared on the other side of the vessel, the above-mentioned hook was passed into the eye, and the bundle uncovered from the other end of it, when it was easily drawn out from under the artery, and the ligature left under the vessel.

In this part of the operation, Dr. Mort argues the necessity of being particularly attentive to the ligatures upon the arteries; one is, to convey the ligature round the artery from below upwards, as the only way to prevent injury of the plexus; and the other is, to fix the hook in the eye of the needle, before the bundle is withdrawn from its other end, because, after this has been done, the bundle moves all directions, and it is then difficult to get the hook into the eye.

With respect to the foregoing instrument, I say otherwise, that they are superseded by the needle lately contrived by Mr. Weiss.

Dr. Mort now made a incision, pressed it with the fore-finger down to the artery, and tightened it very gradually, in order not to stop the flow of blood through the vessel at once. A moderate constriction was kept up some seconds, so that the effect of the ligature upon the heart and lungs might be observed; and as the *Arteria communis* was rendered in the functions of these organs, Dr. Mort tightened the ligature, and stopped the current of blood through the vessel. At this instant, the pulsation of the right ventricle and radial arteries ceased. The nose was tightened still more with the above-mentioned ligature, and then a second knot was made. Dr. Mort was greatly pleased at finding his patient's countenance remain perfectly unchanged, and no complaint made of pain in any other part. Immediately after the ligature had been applied, the anastomotic swelling lost one-third of its size, and the carotid point lay left through its whole extent. The divided trachea and bronchi were now brought into their natural position, the wound closed with three sutures and adhesive plaster, and a compress applied. In the operation three small arteries were tied: the first lay under the sternum, and seemed to be a branch of the *Arteria innominata*; the second was a descending branch of the superior thyroidal; and the third a branch of the inferior thyroidal. From two to four ounces of blood were lost, most of which came from an injured small branch of the subclavian. The operation took up about an hour. The curved spatula recommended by Dr. Cohen, were found very useful for holding the carotid and paravertebral space, while, by their uniform pressure, they materially assisted in restraining the effusion of blood from small vessels, and in taking up little rooms, were infinitely more convenient in a deep narrow wound, than the fingers of an assistant.

The day after the operation, the veins of the right forearm and hand had a knotted appearance. When the circulation in them was promoted by pressure, they became supple for some distance above the knotted part, but filled again immediately, the phenomenon returned; a circumstance that seemed to show, that the thrombus in this area, notwithstanding the ligature, while the artery thickens, will meet us with great energy, though no pain could be felt in the radial and radial arteries. On the contrary, the pulse was very plain in the front branch of the *Arteria innominata*, just above the upper angle of the orbit. The left external carotid lost with unusual ease. In a few days, however, the pain became perceptible again at the right arm.

My notes will not allow me to enter into all the details of this interesting case; suffice it to mention, that the patient suffered considerable febrile disturbance at some periods after the operation, and it was necessary twice to have recourse to sanguification. He was also affected with a severe cough. The discharge from the wound was copious and foul. The respiration was equal to the subsequent day. On the twentieth day, the patient was sufficiently recovered to walk in the garden. On the twenty-first day, the finger was strictly closed; the patient could move his right arm with the same freedom as the left, and he was gaining such strength that no further was entertained about the antiseptic result of the operation.

On the twentieth day, hæmorrhage came on from the wound: it was stopped by the introduction of ligatures and the employment of pressure. About twenty-four ounces of blood were lost, whereby the patient was so depressed that the pulse was no longer distinguishable. On the twenty-fourth day, in the evening, he lost four ounces more blood; on account of his weakness and the painful state of his arm, two grains of opium were administered to him. After one or two hours of bleeding, he died on the twenty-sixth day.

When the body was opened, no traces of inflammation or its consequences were found either at the arch of the aorta, the origin of the *Arteria innominata* or the trunk. The veins were now all open longitudinally, and a probe then easily passed through it into the *Arteria innominata*, when the instrument went through the latter vessel into the cavity of the wound. The lower end of the *Arteria innominata* was smooth and soft; but about half an inch from the place where the ligature had cut through the vessel, marks of inflammation were noticed, and a coagulum adhered to the sides of the artery with considerable firmness, so that much had probably undergone, by means of adhesive inflammation, to close the vessel, but had been prevented from completing the salutary process by the destructive inflammation. One portion of the parietum of the *Arteria innominata* was thickened by inflammation, and an anastomotic branch, as large as a crow's quill, sprang from this artery.

The liver was found as corpulent as usually as it was typically, having largely to the trachea, and under the clavicle to the axilla. The trunk of great vessels, viz. the *Arteria innominata*, the subclavian, and the carotid, was destroyed by electricity in the extent of about an inch, and the ends of both the last vessels buried into the wound. At this place the pleura was considerably thickened by a layer of organized lymph.

The outer surface of the wound was covered with a coagulum, and its edges so much thickened, that a probe could hardly be passed into it. The coagulation extended up to the diaphragm into the external and internal cavity. The *Arteria innominata* was perforated as far as the entrance of the diaphragm. The diameter of the trachea and other organs of the right arm was natural. The external mammary artery was enlarged, but not the internal. The diaphragm was torn, and several lymphatic glands under it in the state of suppuration.

Though the result of the operation was unsuccessful, it seems, as Dr. Mort correctly remarks, some interesting points; namely, that tying an artery of such magnitude, and so near the heart, may be done without occasioning any disturbance either in the functions of the brain, the heart, the lungs, or the right arm.

The suppuration, which continually extended itself more and more deeply, is as shown by Dr. Mort as the cause of the patient's death; for, as no bleeding took place for several days after the detachment of the principal features, it is plain that this must have fulfilled its duty, and that the artery had been closed.—(*New York Med. and Surgical Register*, 1815, vol. 1.)

[This new and formidable operation, the practicability of which Dr. Mort has thus demonstrated, and the safety of which is now decided, it may fairly be expected in which it may become necessary, is justly considered one of the most splendid achievements ever accomplished, and is destined to give the author's name immortality; and this, with the successful case of ligature of the *Arteria communis*, confirms upon American surgery unspeakable laurels. As an evidence of the estimation in which this operation is held in Europe, I feel a national pride in inserting the following extract of a letter from that distinguished surgeon, Professor Codon, of Dublin, written to Dr. Mort after his case of ligature on the *Arteria innominata* had reached him:—I think this trifling is the able operator to the most important, since efforts have been made by the criminals to detract from the merit of the operation; and it has been publicly stated that the same operation has been performed in Europe, and even by Dr. Codon himself. That this is not the fact will be shown from the extract which follows, and which I produce without any further comment.]

"I shall not attempt to say how much the profession is indebted to you for this bold and splendid operation. That it did not succeed I regret on your account; that it will however succeed, there cannot be a doubt in

the end of any remaining man. Their feelings during the first twenty-four days after the operation are to be noted. The degree of edema continued to increase and was well marked, while the slight degree of uncertainty as to the lower limb was still in those feelings to the highest intensity. I have never read the account of an operation in which I would rather take from the operation.—*Revue*.

The aneurism of the aorta was also told by Gracil, on the 24th of March, 1882, in the Hospital of the University of Berlin, on account of a vascular aneurism. The aneurism was exposed and treated with the operation in which a ligature was applied by the means of a lateral incision, interrupted by the pharynx, the vessel being first in most about an inch from the anterior of the aorta, and two inches from the heart. As soon as the ligature was tightened, the pulsation of the arteries of the right arm, right neck, and right temporal artery ceased, and the same instant the throbbing of the aneurism stopped, and the heart became fixed. The constriction of the cord produced no disturbance of any function. The patient remained as well for several weeks afterward, and in doubt was experienced of his recovery. However, when the wound was again healed, hemorrhage came on, and though it was suppressed, and began to be again checked, the bleeding occurred, and the patient died on the day-seventh day. Before the ligature of the aneurism was found closed with ligature. Gracil has written a different story to the method in which the operation was done, the daily pulsation of the case, and preparation from it, and placed in the Royal Anatomical Museum at Berlin.—*Ann. Journ. de Chirurgie*, vol. 1, p. 587. In Mr. Wagon's practice of tying the subclavian artery as aneurism of the aorta aneurism itself, we shall presently speak.

CARDIAC ANEURISMS.

There is no part of the body where the diagnosis of aneurism is more liable to mistake than in the neck. Here the disease is particularly apt to be confounded with tumors of another nature. We have already cited in this article examples in which aneurism of the arch of the aorta so resembled those of the cord as to have deceived the surgeon who was consulted. The swelling of the lymphatic glands, or of the cellular substance, which surrounds the carotid artery, the enlargement of the thyroid gland, and especially aneurism, may resemble an aneurism by the pulsations communicated to them by the neighboring artery. On the other hand, aneurism of long standing, which no longer throbs, and the impregnation over which are changes in color and likely to burst, may be more easily mistaken by an incautious practitioner for chronic thrombus, as the neck is remarkably often the seat of such disease.—*Anger, Traité des Maladies Chroniques*, t. 2, p. 155.

Scarpa mentions one unfortunate patient who was killed by a knife being plunged in a cardiac aneurism, on the supposition that the case was an aneurism.

I need scarcely assure, that by opening a cardiac aneurism a surgeon would expose himself to the danger and mortification of seeing the patient die under his hands, as happened in the example cited by Harlan.—*Cyclopædia Anatomica*, lib. 86.

The possibility of tying the carotid artery in cases of aneurism has assuredly without any dangerous effect on the function of the brain, is now completely proved. Petit declared that the advocate Vieillard had an opportunity of the operation of the right carotid, for the case of which he was ordered a very severe diet, and directed to avoid all violent exercise. Three months afterward the patient had evidently diminished, and at last was converted into a small, hard, elastic knot, without any pulsation. The patient having died of apoplexy seven years afterward, the right carotid was found closed up, and separated from its insertion, as far down as the right subclavian artery.—*Ann. des Sciences de Paris*, an. 1783. Harlan observed a woman whose left carotid was impregnated.—*Opuscule Pathol.*, lib. 16, par. 3. An example of the total closure of both carotids in consequence of aneurism, is stated by Bouchard to be recorded by Harlan.—*Effluvia translat.* of Mr. Harlan, vol. 1, p. 303. Harlan, vol. 4, p. 256, et. 5, of his translation, of *Revue de Chirurgie*, mentions a case

in which the carotid artery was wounded in the case of a nervous aneurism. The aneurism was found to have been that had not the surgeon immediately tied the trunk of the vessel. The patient died nearly seven years after. This is probably the earliest instance of aneurism in which a ligature was applied to the carotid artery. Mr. Abernethy's case is perhaps the second, and that in which Mr. Hastings, a naval surgeon, had the carotid artery tied in a case of aneurism, and which was used by the operation, is well known, as having occurred in the year 1792.—*Ann. Med. Chir. Journ.*, vol. 1, p. 25.

Dr. Harlan knew an instance in which one carotid was severely obstructed, and the disease of the other considerably lessened, without any apparent effect on the brain.—*Ann. Journ.*, for the *Interpretation* of Med. and Chir. Knowledge, vol. 1, p. 121. The Army Surgeon has also recorded an example in which total closure was obtained by the pressure of an elastic cord on the artery, and yet during life no pulsation in the pulsation of the trunk and aneurism.—*Ann. Med. Chir. Journ.*, vol. 1, p. 252. A similar case is cited by Petit.—*Opuscule Chir.*, t. 1, p. 15.

Mr. Abernethy was under the necessity of tying the trunk of the carotid in a case of extensive internal wound of the neck, where the internal carotid artery had aneurism of the external carotid was aneurism. The patient at first went on well, but in the night he became delirious and convulsed, and died about three hours after the ligature was applied. This case is noted by some authors, and the influence which I have seen, that the case died from the great quantity of blood which he lost, and the severe reaction due to the parts in the neck, than from any effect on the ligature of the artery on the brain.

In another instance in which the carotid artery was tied, on account of a wound of the external carotid by a musket ball, complicated with fracture of the condyle and coronoid process of the lower jaw, every thing went on favorably until the seventh day after the operation. Next the intellectual faculties on the functions of the organs of sense had been all destroyed. But at that period stupor, vomiting of bile, prostration, a small aneurism, pale, faintness of the face, and loss of strength came on, followed in the evening by a violent paroxysm of fever. On the eighth day three copious hemorrhages took place from the whole surface of the wound, and on the tenth the man died. In this case, however, the affection of the brain, and the other unfavorable symptoms, would be ascribed by nobody to the effects of the ligature on the carotid, but every one would see the cause in the severe and extensive local mischief produced partly by the musket ball, and partly by the work in which the operation was performed, the surgeon having exposed his incision from the parotid gland to within an inch of the epiglottis.—*Ann. Journ. Général de Méd.*, 42, p. 325.

That the carotid may be tied without losing the functions of the brain, and that aneurism of the artery which of being cured by the operation, is now fully proved. The following is the second instance in which I have been present at the operation of tying the carotid trunk on account of a wound.

A soldier of the 4th regiment was wounded in the neck with a part of the bottle of Warrington, and was brought to Epsom. After he had been some time in the hospital, the bleeding, which had stopped, renewed with great violence, both from the wound and the external wound itself; and it was therefore found necessary to tie the carotid artery, which was done by Mr. Collier. The operation was performed by making an incision along the carotid in the sternocleidomastoid muscle, raising the aneurism from the wound, and tying the artery. A c., and looking into the wound the lower thyroid veins, which were in every instance a very large size, so as to be visible in the wound. The wound being separated from the artery was tied. Though the operation was done by candle-light, it was skilfully performed, and without great credit to Mr. Collier. A short time after he was taken to a military work.—*Ann. Chir. Journ.*, vol. 1, p. 371.

Another example in which the carotid artery was tied and the patient cured, in a case where it was wounded within an inch, was performed by Dr. John Brown, surgeon to the county of North Devon.

Ohio Medical Hospital Reports, vol. 3, p. 211, 1871.) In this instance, the internal carotid vein "did not appear, nor was it a sign of the slightest inflammation during dissection."—(P. 212.) A case, very analogous to the foregoing, is recorded by Mr. Hodgson, and the result equally successful. "The patient was affected as thick as the operation; it was not even seen." A gradual improvement of the point of distention marked the gradual subsidence of the tumour, which proved similar to the foregoing. Her next day changed position in the state of the patient's mind after this operation, who remained as she had been previously, taciturnity and depressed.—(P. 212.)

Another instance is mentioned in which the carotid artery was wounded by a gunshot, and the hemorrhage probably stopped by compression. A similar case is related by Van Buren, in his annotations to the work of Bonetus.—(De Puls. Molyneux.) Maria Leroy has likewise related a case, in which the vessel was wounded by a gunshot, and the wound by the instant application of pressure.—(*Mem. de Chir. Mil.* t. 1, p. 207.) However, considering the size of the vessel, and its inveterate extension far below the neck, and usually compressed, some doubts may be entertained, whether the vessel wounded might not rather have been one of its branches.

November 1, 1835, Mr. Astley Cooper operated on Mary Edwards, aged forty-four, who had an aneurism of the right carotid artery; the tumour resulted from the vicinity of the chest to beyond the angle of the jaw, and descended to within two inches and a half from the clavicle.

The swelling had a strong pulsatory motion. The woman complained of a peculiar tenderness of the artery in the same site, of the head, and of such a throbbing in the brain as prevented her from sleeping.

An incision, two inches long, was made at the inner edge of the sternocleidomastoid muscle, from the lower part of the tumour to the clavicle. This would expose the omo-hyoides and sterno-hyoides muscles, which being drawn aside towards the trachea, the jugular vein presented itself in view. The tenderness of this vein produced the only difficulty in the operation, as, under the different states of breathing, the vessel sometimes became tense and distended under the knife, and then suddenly collapsed. Mr. Astley Cooper introduced his finger into the wound to keep the vein out of the way of the knife, and having exposed the carotid artery by another cut, he passed two ligatures under this vessel by means of a curved grooved needle. Care was taken to divide the recurrent nerve on the one hand, and the vagus on the other. The ligatures were then cut about half an inch asunder; but the intervening portion of the artery was left unaltered.

The pulsation of the swelling ceased immediately the vessel was tied, and on the day after the operation, the throbbing in the brain had subsided, while no disturbance of sleep or energy in any part of the body could be ascertained.

The patient was occasionally afflicted with indigestion, but soon the whole went on at first pretty well. On the eighth day, however, a paralysis of the left leg and arm was noticed, attended with a great deal of spasmodic irritation. Nevertheless, the patient could move her arm rather better, but became unable to swallow solid food. Nov. 13th, the pulse of her arm and leg were discovered. The ligatures came away. Nov. 15th, she was in every respect better, the paralysis with less difficulty, and the tumour was smaller, and quite free from pain. On the 18th, she became very ill; the tumour increased in size, and was still more painful. The wound was as large as immediately after the operation, and discharged a copious serum. Great difficulty of swallowing, and a most distressing cough were also experienced. The pulse was everywhere, and the left arm quite very weak. On the 20th, the patient died, the difficulty of swallowing having certainly become still greater, attended with a further increase of the tumour, the skin over which had acquired a brownish-red colour.

On opening the swelling after death, the aneurismal sac was found inflated, and the clot of blood in it less intermixed with a considerable quantity of pus. The inflammation extended on the inside of the sac, along the par vagus, away to the base of the neck. The glottis was almost closed, and the larynx of the trachea

very inflamed and covered with coagulating lymph. The pharynx was so compressed by the tumour, which had been suddenly enlarged by the inflammation, that a bougie of the size of a goose-quill could hardly be introduced into the pharynx. Mr. Astley Cooper concludes with expressing his opinion that these cases of failure may, in future, be avoided by operating before the tumour is of such size as to make pressure on important parts; or, if the swelling should be large, by opening it, and letting out its contents, as soon as inflammation makes out.—(*See Med. Chir. Trans.* vol. 11.)

Incision was under the care of Mr. Cooper, of Salisbury, the making of an opening, about a month after the operation, governed by discharging seven ounces of vital blood and pus; but three weeks afterward, hemorrhage came on from the sac, and the patient was hurried off by repeated loss of blood.—On dissection, an artery capable of sustaining a probe was found to pass into the cavity of the tumour.—(*See Med. Chir. Trans.* vol. 11, part 2.)

In June, 1836, Mr. Astley Cooper operated, at Guy's Hospital, on a man aged 65, who had a carotid aneurism, attended with pain on the side of the head, throbbing in the brain, blindness, cough, slight difficulty of breathing, vertigo, palpitations, &c. The patient got quite well, and retained his occupation as a porter. There was afterward no perceptible pulsation in the facial and temporal arteries of the aneurismal side of the face.

On the opposite side, the temporal artery broken externally large. The patient was at last quite absorbed, though a pulsation existed in it till the beginning of September. Two weeks incidentally remained perfect; his nervous system was unaffected, and the severe pain, which before the operation used to affect the aneurismal side of the head, never returned.

The swelling, at the time of the operation, was about as large as a pullet's egg, and situated on the left side, about the size made by the difference of the osseous crest, just under the angle of the jaw.

Mr. Astley Cooper began the incision opposite the middle of the thyroid cartilage, on the base of the tumour, and extended the wound in width an inch of the clavicle, on the inner side of the sternocleidomastoid muscle. On raising the margin of this incision, the omo-hyoides could be distinctly seen crossing the sheath of the vessel, and the carotid artery itself was also brought into view. The sterno-cleidomastoides was now separated from the omo-hyoides, when the jugular vein was seen. This vessel became so distended in every situation as to cover the artery. When the vein was drawn to one side, the par vagus was exhibited, lying between the vessel and the carotid artery; but a little in the outer side of the artery.—The nerve was easily avoided.

A double ligature was then conveyed under the artery with a bent iron probe. The lower ligature was immediately tied, and the upper one was cut down tight, so soon as about an inch of the artery had been separated from the surrounding parts above the first ligature, so as to allow the second to be tied at that point. A probe and clamp were passed through the vessel below one ligature and above the other.—The artery was then divided. It is a little more than nine weeks the wound was quite healed, and the patient entirely recovered.—(*See Med. Chir. Trans.* vol. 12.)

Another successful instance, in which the carotid was tied for the cure of an aneurism, is related in a reply to which I always have the greatest pleasure in referring.—(*See Hodgson's Treatise on the Aneurism of Arteries*, p. 220.)

Mr. Thompson tied the carotid artery in a woman, who had an aneurism of the carotid in the left neck. The disease had passed the eye out of its socket. Two small ligatures were applied, which operated on the tumour, but and temporary success. No hemorrhage, nor impairment of the function of the brain took place, and the disease in the neck was effectively cured.—(*See Med. Chir. Trans.* vol. 12.)

Another highly interesting case, in which an aneurism of the carotid artery was effectively cured by tying the carotid artery, is recorded by Mr. Barrymore, assistant in Norwich. This gentleman performed the operation on the 5th of November, 1812. The patient was a female, aged 44. The pulsation of the artery was relieved in proportion to the swelling

Generalized. The violent hæmorrhages also continued; but the symptoms were insupportably bad.—(*New Med. Obs.* Trans. vol. 5, p. 111.)

The carotid artery has sometimes been tied, with the view of enabling the surgeon to cut away everything from the neck and side of the face, when, from particular circumstances in the case there was reason to fear a fatal hæmorrhage without that preliminary measure.—(*New Medical and Surgical Cases, as Observed at Clin. Trans.* vol. 7 and 11.)

An interesting case, in which my friend Mr. Vincent tied the carotid trunk for an aneurism, is published in the 10th vol. of the latter work.—(P. 212, &c.) In this example, the internal jugular vein did not appear to be at all in the way during the operation; none of the fibres of the new ligature, however, could not be immediately drawn tight, and were therefore divided. A single ligature was applied; the pulsation in the tumour did not entirely cease, at first, when the artery was tied, but it did so two days afterward; and the swelling was rapidly diminishing. The ligature came away about three weeks after the operation, and there was every hope of a cure; but, between the fourth and fifth week, a considerable swelling occurred between the tumour and the jaw, impeding deglutition, but not the breathing. This swelling was followed by febrile symptoms, increased difficulty of swallowing, an attack of vomiting, and impeded respiration. In the hope of affording relief, an incision was made in the tumour from which a small quantity of pus had collected inward; but it was in vain, for the patient was dying. On dissection, the carotid artery was found perfectly sound as far as the division of the aneurismal sacculi. But above where the ligature had been, the vessel was open and inflamed, and was tied to it. The most remarkable circumstance noticed was protrusion of air, entering by the inner surface of the artery, and other large arteries, and forced out under the heavy aponeurosis. The life of the swelling in the neck depended upon effusion of serum in the cellular membrane.

In order to get at the carotid artery in the author's manner, Mr. Abernethy has recommended making an incision on that side of it which is next the trachea, where no important parts are exposed to injury, and then to pass a finger underneath the vessel. The par vagua must be carefully excluded from the ligature; for to tie it would be fatal.—(*Surgical Observations*, 1804.)

The case of carotid aneurism by the operation has now been so often successful, that even to refer to every case upon record would demand more space than I can afford. A successful instance is related by Macartney (*Edin. Med. Surg. Journ.* April, 1804); another by Dr. Ford, who used two ligatures, and divided the artery in the space between them (*New-England Journ. of Medicine and Surgery*, vol. 3, p. 205, Boston, 1814); another by Mr. Giles Lynde, proving the sufficiency of a single ligature.—(*Med. Clin. Trans.* vol. II, p. 57, &c.) The case in which Mr. Goodall tied the carotid, in order to prevent hæmorrhage in the removal of a fungus involving the parotid gland, is contained in vol. 7, p. 112, &c. of the latter book. The example in which the vessel was tied by Dr. Franks, in the length of Hareburgh, for the cure of a fistulous purpura, is reported in the *Lancet*, N. 192. Some discussion of the swelling, and increased power of swallowing followed; but suppuration took place, and the case ended fatally.

The most anatomical privileges of the parts concerned in the operation of taking up the carotid artery, are those by Tieboutin and Rouviere.—(*Ann. Chir.urg. Journ.* Amsterdam, &c. 1, vol. 7, p. 93.)

For the particulars of a second aneurism caused by the ligature of the artery by H. Wilson, see *Ann. of Chirurgery de l'Europe*, article, par P. J. Vanderlinden, Paris, 1815. Watson, at Leamington, in the year 1811, tied the carotid artery for the cure of an aneurism with complete success. He applied only a single ligature.—(*Annals of the Royal Med. Soc.* vol. 1, p. 52.) In this translation are reported several instances, in which ligatures and other caustic surgical operations applied to the carotid, Dr. Hall, sister of Hæccher, has also operated with success.—(*Ann. Lond. Med. Repository*, vol. 13, p. 95.)

Dr. Beane has lately tied the common carotid artery in an aneurism situated in the sheath, with complete suc-

cess. Professor Pattison, of the University of London, when resident in Baltimore, cured an aneurism opening at the external jugular by tying the neck of the carotid. I witnessed this operation, and saw the successful result.—(*Edin.*)

Of the mode of tying the carotid above the aneurism, when it is situated so low that the ligature cannot be applied below it, I have also spoken. The facts, by which the propriety of this practice has now been completely established, have also been stated; they appear to me to reflect considerable credit on Mr. Wardrop, to whom this method of operating has been removed and extended. The practice of tying the carotid for the cure of aneurism of the artery transmits that to be tied in the existing section.

NEW OPERATION FOR ANEURISM OF THE ARTERIA AORTICA.

It having been established, that aneurisms may be cured by simply inserting the trapezoid of the blood flowing through them, and that, although a temporary may yet continue to flow, for some time, the layers of elasticities lymph will be the way to suggest, and ultimately bring about a complete consolidation of the swelling, it occurred to Mr. Wardrop, that in aneurism of the artery aorta, the progress of the disease might be arrested by tying its two great branches, the carotid and subclavian. Although a certain portion of blood would still continue to pass along the aneurism to those branches of the subclavian in the carotid of the ligature, the ligature being necessarily placed on the subclavian artery after it emerges from beneath the subcutaneous muscles, Mr. Wardrop conceived, that this would yet be the circulation of the blood in the aorta, but that the future progress of the disease would be prevented, and even its permanent obliteration of the aneurismal cavity would be accomplished.—(*On Aneurism*, p. 58.) The knowings of this process, indeed, he thinks, may be useful in the cure of many aneurisms, which have hitherto been considered beyond the reach of art. In an aneurism of the aorta, Mr. Macleod found that system had only completed a cure of the disease on this principle. The carotid artery was plugged up, and the first aneurismal swelling was filled with a roughness, using only a comparatively small channel for the passage of blood into the subclavian artery.—(*See Appendix to Wardrop on Aneurism*.) Mr. Wardrop has seen two cases, and several are on record, which illustrate some important pathological fact, and prove beyond a doubt, that blood can coagulate in an aneurism so it is strengthened the power of the art, and ultimately its efficacy, without the circulation in the vessel being the first instance either suddenly or entirely interrupted.

It was the knowledge of this fact that led Mr. Wardrop to perform the operation, which he has named Nature, in the case alluded to, had already effected a curative process by contracting the circumference of the carotid artery; and when he found that some he would want to stop the enlargement of the aneurism, he determined to place a ligature on the subclavian. In doing this, he conceived that he was strictly following a process which nature herself had commenced.—(*Id.*) The case of Mrs. Denmark, aged 45, mentions that the subclavian artery, and thus avoid an aneurism of the artery aneurism, is highly interesting. The particulars may be read in his own publication, or in *Edin. Journ.* for 1817. Suffice it here to state, that the case was completely cured. In the appendix to Mr. Wardrop's publication, and in the *Lancet* for November, 1818, is another highly interesting case, containing the account of the privileges explained by the foregoing synopsis. It is an aneurism in which Mr. Jones, of Bath, Bathurst, successfully made an incision of the aneurism and cure of the aneurism by tying the latter vessel. In the year, he joined a scholar and householder, thirty years of age, was so much as moved regularly the markets and sold Mr. Dyer, seven years from his house. In the course of the case, three remarkable circumstances occurred. 1st. An obliteration of the large arteries of the right arm. 2dly. A profuse sanguine. 3dly. A rupture to paralysis of the right side, suggested by Mr. Jones as having arisen from a greater quantity of blood, than sent to the left hemisphere of the brain than 18 1/2 right. However, in such aneurism has not aneurism.

other operations in which the vessel was tied, the truth of the explanation seems doubtful. The following account seems entitled.

[It affords me high gratification to record, that Professor Hager, of this city, has lately performed this operation for the first time it has been attempted in America, by tying the arterial artery for the aneurism of the aorta (aneurism, involving the whole vessel, and not of the aneurism). This is the first time in America in which aneurism has been treated by tying the artery on the posterior side of the vessel. The report of the case, and its successful result, is contained in the *American Journal of the Medical Sciences*, No. 10, for February, 1836. Since that report was published the patient has died, and his remains having been recovered, fully establishing the success of the operation. I have had an opportunity of examining the preparation, and found the vessel entirely aneurismal and the patient died the aneurismal sac, although the ligature was applied very high on that vessel. The death was occasioned by the decomposition and distension of the trachea and lungs, which was seen lying on the side of the neck, and as it was connected with the operation, but was the consequence of the long existence of the disease before the operation was attempted. — *Doyle*.]

OF ANEURISM OF THE AORTA, AND TAYLOR'S TREATMENT.

This afflicting and fatal disease is by no means infrequent, and the seat of the aorta is its usual common situation. Dr. Hager was of opinion that the latter circumstance depended on the terrible manner in which the blood, propelled from the left ventricle of the heart, must be driven against the angle of the rigidity of the vessel.

Mr. A. Harris, consistent adherent of the thoracic aorta must depend, perhaps, than that of any other vessel in the body. "I have had (says he) an opportunity of examining patients who had died of this disease, but have not seen more than three instances of external aneurism." — (*The Diseases of the Heart*, &c. p. 753.)

These propositions, however, would not correspond to common observation, external aneurism, taken collectively, being supposed to be about as numerous as those of the aorta alone, a calculation long ago made by Dr. A. Meigs, p. 200.

It was the opinion of Dr. W. Hager that the aneurism was composed of the dilated coats of the artery, which parts nature thickened and studded with ossifications after the origin of the disease, for the purpose of resisting its increase. Mr. Hodgson, also, in his interesting publication declares his decided belief, and advances facts to prove, that many aneurisms of the aorta are formed by dilatation. *Scarpa* argues, however, that the generality of aneurisms of the aorta are the consequence of a rupture of the proper coat of this large vessel, and that the cellular sheath of the artery is what becomes distended (and the thickened and ossified aneurismal sac).

Dr. W. Hager considered the ossifications of the sac as consequences of the disease; but Hager inferred from such ossifications in the aorta as the very cause of the aneurism, by rendering the artery insensible, and incapable of yielding to each pulsation of the heart.

It is unquestionably true that aneurisms of the aorta are most common in persons who are advanced in life, and it is equally well known, that the aorta of every individual, whether affected with aneurism or not, is almost always injured in some place or another with ossifications, or rather with calcareous concretions, dark protuberances appear to contain a dense or aneurismal of the interior and inner coats of the vessel, so that in length the force of the blood makes the artery give way, and the fluid collecting in the course of the aneurism or rupture, gradually distends the external sheath of the artery into the aneurismal sac, which is not a disease in fact of considerable duration, and ended with mild symptoms.

If any person who is not prejudiced in favor of the common doctrine with regard to the nature and progressive course of this disease (says *Scarpa*), will examine, not hastily and superficially, but with care and by dissection, the aortic structure and nature of the aneurism of the aorta, including such points as attend the proper and common coats of this artery, and

in succession those which constitute the aneurismal sac, in order to ascertain distinctly the nature and limits of both, he will clearly see that the aorta, especially speaking, contains nothing in the formation of the aneurismal sac, and that, consequently, the sac is merely the cellular membrane, which is the aneurismal sheath of the artery, or that soft cellular sheath which the artery received in common with the neighbouring parts. This cellular membrane, being raised and compressed by the blood effused from the aneurismal or ruptured artery, assumes the form of a compressed bladder, covered externally, in aneurism with the artery, by a strongly tendinous, such as the pelvis in the aorta, and the peritonium in the abdomen.

Several facts themselves upon the differences of mere dilatation of an artery from aneurism, a subject which has been already fully noticed in the foregoing pages. — (*Scarpa on the Aneurism, Pathology, and Surgical Treatment of Aneurism*, transl. by Winslow, p. 116-120.)

As I have already explained in the preceding chapters, the weakness of this aneurismal aneurism are not adopted by the generality of surgeons; at least, the doctrine is not correct by whom to the extent which he has treated upon, and it would be tedious repetition to bring before the reader again the facts which prove that the statements are false in every respect. A case, however, noted by *Hager*, which I have met with since the foregoing pages were printed, seems to me to be an instance in which a typical aneurism, contracted with pulsation, had been mistaken for an aneurism and punctured, whereby the patient lost his life. On describing the fact, *Hager* says, "the three coats of the artery participated in the distension, and the case was one of the most common species which I have ever seen of a true aneurism." — (*Neurotic Elements of the Heart*, &c. p. 107.)

All arguments brought against the possibility of a dilatation of the outer coat, and founded on the insensible structure of that membrane must likewise be completely refuted by another fact demonstrated by marked preparations, collected by *Debus* and *Requien*, where the outer coat of the aorta is alone distended, protruding through the outer basis in the form of a distinct swelling somewhat like a tumor. — (*Requien*, &c. p. 91.)

In whatever manner aneurisms of the aorta are formed, there are no diseases which are more justly dreaded, or which were completely all the surgeon as well as the patient with despair. No aneurism, indeed, can be more truly dreadful; for the sufferings which are occasioned hardly ever admit even of palliation, and the chances of recovery are so very few, that no consolatory expectation can be indulged of avoiding the fatal end to which the disease invariably brings the miserable sufferer.

The progress of aneurisms of the aorta is scarcely ever known with certainty before they have advanced so far as to be attended with an external pulsation and a tumor that admits of being felt or even seen. In very thin subjects, the throbbing of the abdominal aorta is sometimes transiently plain through the integuments and viscera, and then this occasionally given rise to the suspicion of an aneurism; a circumstance which deserves to be remembered by every surgeon desirous of not presenting a wrong opinion. The peritoneal pulsations, however, which are liable to be mistaken for those of aortic aneurisms, are of various kinds, and form a subject to which the attention of *Dr. Allen*, of Boston, the late Mr. A. Harris, and others, has been very recently directed. — (*See Anderson*.)

While three coats aneurisms of the aorta are compared with no degree of external involution, the symptoms are all external, and might depend on any disease of the heart, ruptured pericardium, pleuritis, pulmonary &c. However, some difference depends upon the volume, position, and nature of the aneurism. As *Laennec* observes, aneurism distends, when in a moderate degree, hardly produces any effect, but the most considerable false aneurisms may give rise to very serious disorders. The first and most common of these effects is, the compression of the heart and lungs. — (*See Laennec on Diseases of the Heart*, by Parker, p. 179, &c. 2.) Very late and irregular throbbings frequently occur between the fourth and fifth true ribs of the 9th ribs; the same irregularity of the pulse prevails in older persons than organic affections of the heart; a gradual jerky of the pulse is the true aneurism; the inspiration

is exceedingly obstructed, the valve closed; and in a brief advanced period of the malady the patient is at times almost suffocated. "The position of the internal trachea on the trachea, bronchi, and lungs, is sufficient to account for this difficulty of breathing. In many instances the irritation and compression produced by the tumour occasion an absorption of the greater part of the lungs, and abscesses and tubercles throughout the portion which remains. Even the function of deglutition suffers interruption in consequence of the pressure made on the œsophagus, which may even be in a state of ulceration. Thus, it is very simple, possibly, perhaps, we find that the cavity of the stomach was nearly obliterated from the pressure of the aneurism; and the accumulation of feces in the colon lay in the œsophagus, having material that could through no other way be cast."—(*Travels for the Improvement of Mind and Character*, vol. 2, p. 53.)

After what has been stated, it cannot be surprising, that when the disease manifests itself externally, affections of the lungs or structure of the œsophagus should often be suspected.—(*Holman*, p. 91.)

"An aneurism of the aorta, unattended, not discovered till after the patient had died of suffocation, gave rise to great difficulty of drawing air into the chest without any other symptoms calculated to throw light on the nature of the disease. The aneurismal swelling was situated behind the first bone of the sternum, and pressed upon the trachea. The first of this rule was pushed in by the tumour so as to prevent a necessary prominence on the inner surface, which, however, diminished in area in a very slight degree. Mr. Lawrence adduces this fact to prove that species of the aneurism may be the cause of great difficulty in breathing. "The termination of this case (says he) is the more remarkable, inasmuch as in another patient an aneurism rising out of the arch of the aorta, and pressing on the corresponding part of the trachea, seems to produce obstruction of the internal trachea, under which there was a slight appearance of congested blood, caused in affection of the length at all. The person died of a different complaint, and the discovery of the aneurismal tumour, which was very small, and filled with fine laminated coagula, was quite accidental."—(*Med. Obs.*, *Travels*, vol. 8, p. 375.)

Thus we find in thoracic aneurisms, at least previously to their attainment of a certain size, that no regularly prevailing signs with regard to difficulty of breathing, the symptom which, a priori, one might suppose would necessarily be present.

New diseases, according to Lawrence, are so immediate manifestations of the thoracic aorta. He affirms, that "it cannot be known with certainty till it shows itself externally. It can hardly be suspected even when it compresses some important organ, and greatly deranges its functions. When it produces neither of these effects, the first indication of its existence is often the death of the individual, as instantaneously as if by a pistol-bullet." One case, recorded by Mr. Pott, confirms the same fact, for the patient had only symptoms leading to a suspicion of enlargement of the neck, and died suddenly of apoplexy."—(*Observations on the Wind and Neck*, &c. by Pott, &c.) Lawrence has known persons die off in this manner who were believed to be in the most perfect health. He admits that persons may sometimes enable us to detect in tumours of large size existing within the mediastinum, or even in the neck; but not to discriminate the nature of the swelling. His experience did not seem sufficient to let him pronounce how far the difficulty of diagnosis was likely to be increased by the aneurism. However, aneurisms of the abdominal aorta he says, are recognised with the utmost facility by means of this intervention. In this case we are sensible of considerable pulsations, which peculiarly affect the ear, and the quantity of which is not at all increased by the hand, even when infinitely sensitive to the touch. As high up as the neck artery the contractions of the arteries never is so well distinguishable. The speed of the pulsations is described as clear and loud."—(*Lectures on the Health of the Chest*, p. 375, &c.)

I have mentioned that the symptoms of thoracic aneurisms, particularly in the formation of an aneurism, are often resemble those of pneumonia, and the latter is sometimes actually supposed to be the disease under which the patient is labouring. But there is

one distinction between the cases, which is pointed out by Mr. Hodgson, and may be of use, in explanation with other circumstances, in limiting the diagnosis. "In pneumonia, the expectoration is either purulent or thick and white; but in aneurism what is coughed up is accompanied with hæmorrhage in the lungs, as far as I have observed, it always consists of a thin frothy mucus."—(*The Diseases of Aneurism*, &c. p. 93.)

According to Hodgson's experience, the cough coming on at irregular periods, is violent, and attended with great efforts, the expectorated matter being raised by the violence. He agrees with the thinkers respecting the genuine quality of what is expectorated, while thoracic aneurisms are not complicated with hæmorrhage; but he says that the matter coughed up also frequently consists of mucus or stringy mucus with fine and purulent blood, which seems, when thrown into water, seem as if they were composed of a lot of stringy substances.—(*Garrison's Treatise of the Aneurism*, &c. p. 125.)

From a review of many cases of aneurism, according to Mr. A. Barnes was inclined to think, that when the ascending aorta is aneurismal, the breathing is more affected than when the arch of the vessel is enlarged, but that in the latter case the impediment to deglutition is greatest.—(*The Diseases of the Heart*, &c. p. 244.)

According to Lawrence, false aneurisms are most common in the descending aorta; and true ones in the ascending portion of the vessel and its arch. He has never met with any species of false aneurism in the latter situation, but such as is homogeneous in the true or simple form of the artery.—(*See Lectures on the Diseases of the Chest*, p. 376, &c. by Pott, &c.)

The way in which aneurisms of the thoracic aorta prove fatal, is subject to considerable variety. These swellings do not always destroy the patient, by hemorrhage; in numerous instances, the magnitude of the disease so impedes respiration, that death seems induced by suffocation, and not a drop of blood is found internally effused. Frequently no less the description of Mr. John Bell, before the death and fatal hemorrhage has had time to occur, the patient persists in suffering so great for nature to beat. The aneurismal manner so fills the chest, so compresses the lungs, compresses the trachea, and curbs the course of the descending blood, that the system with a pain strivings of the expanded blood, is quite exhausted. And thus, though the patient is saved from the most terrible scene of all, he suffers great misery; he experiences in his chest severe pains, which he compares with the stinging of knives; terrible palpitations; an awful sense of sinking within him; a hoarse within his throat, as if of the running of waters; a continual sense of his condition; sudden startings during the night; fearful tremors and dangers of suffocation; and with unceasing night, miserable thoughts by day, and the gradual decline of an exhausted system, he grows weak, frequent, and expires."—(*See Aneurism of the Human Aorta*, by John Bell, vol. 2, edit. 3, p. 224, 225.)

Mr. A. Barnes was two examples, in which the patients died instantaneously, though their aneurismal tumours were very small and had not burst. But these patients were in the early stage of pregnancy.—(*The Diseases of the Heart*, p. 224.)

The situation in which aneurisms of the curvature of the aorta burst, are different in different cases. Sometimes the swelling bursts into the cavity of the chest, or that of the pericardium, and the patient drops suddenly down. According to Lawrence, the severity of the disease is by far the most frequent situation in which the thoracic aneurism of the aorta bursts.—(*The Diseases of the Chest*, p. 377.) When the coats of the aorta give way within the pericardium, where they only receive a slight external meniscus covering, drops up to be thus retained at the same time, so as to bring its exposed surface of blood, which compresses the valves of the heart, and produces immediate death. In other examples, the blood is effused into the cavity of the chest, and the patient, after violent coughing and efforts of blood from the mouth, expires. Sometimes, after the tumour has become closely adherent to the lungs, it bursts into the vessels, through which the blood is readily effused. An example of this termination of the disease was observed by Lawrence; who also saw about six or eight, in which, if the patient had lived a little longer, the same catastrophe is all probably would have happened. Blandin says, that he is not

arch of the aorta may occasion a rupture so much like that of a tubercular abscess, as to be in danger of being mistaken for the latter disease. An example of this kind is related by Mr. Allan Burns:—"A man," says he, "from which several of the most distinguished practitioners of Edinburgh, and almost every surgeon in Glasgow, were consulted. The nature of the disease appeared to be so doubtful, that an operation in the thoracic artery was done, that on that subject there was no difference of opinion. Some were, however, of opinion, that an operation might be performed, while others were fully convinced, that the case was tubercular. For myself, I must confess, that I was fully persuaded, near to the very stage of the disease, an operation might have been beneficial." &c. (*Surgical Anatomy of the Heart and Aorta*, p. 231). After death the vessel which was supposed to have been ruptured, internally affected, was found perfectly healthy.—(p. 25.)

After dealing at the particulars of this interesting case, Mr. A. Burns observes, that "it corroborated Sir James Cooper's theory, that aneurisms of the aorta may assume the appearance of being situated in one of the arches of the neck: an inference drawn from the observation of a case which came under his own observation, and of which he has the goodness to inform, at whose house I was, along with a Dutch physician, of the position of the vessel. In one case, the aneurism was situated on the right side of the aorta, and occupied a part of the artery immediately in Sir A. Cooper's line, the tumor arose from the left side of the arch, from between the roots of the left subclavian and carotid arteries. It formed a flattened, fusiform cyst, the bottom of which projected at the top of the neck, from behind the sternum, and so many vascular anastomoses of the root of the brachial artery, that the practitioner who consulted Sir A. Cooper, actually mistook the disease for an aneurism."—(*ibid.*, p. 232, 233, 234.)

The preceding sentence has received full confirmation from the observation of an aneurism of the aorta. "I have seen," says Mr. Hodgson, "several cases of aneurism arising from the superior part of the arch of the aorta, which protruded above the sternum and clavicles, and in one instance, the space between the sternum and the sternum was so considerably, that it was proposed to tie the curved artery far as posterior, which descending passed in space from the origin of the aorta immediately from the arch of the aorta."—(*On the Diseases of Arteries and Veins*, p. 30.)

As we have already noticed aneurisms of the aorta are most frequent at its curvature; but they are also met with on the other portion of this vessel in the thorax, and likewise on that part of it which is below the diaphragm. In subjects predisposed to aneurism, such swellings are frequently seen affecting various parts of the aorta at the same time.

When the disease occurs in the abdominal aorta, a preternatural dilation generally becomes perceptible at some particular point. The possibility of the latter inference with the direction of the vessels, the breathing is rendered difficult; at the swelling, moving the chest of the diaphragm; the patient suffers of great extraordinary internal pains; sometimes he is affected with convulsions; sometimes with dyspnoea; and one unfavourably with incontinence of the urine and stool. At length an intense external swelling is formed, which increases alternately, and if the patient survives some months, destroys him by a sudden violent termination— *hæmorrhage of blood*.

Aneurisms within the thorax and abdomen, being entirely out of the reach of operative surgery, have been but cursorily attended at an aneurism of the aorta, and when this has been done in vain cases, it has generally been only with a view of palliation. In regard to the three of the circulation by the lungs and the heart, another every thing that may be done to relieve the body, or guard the action of the heart, keeping the bowels well open with laxative medicines, and breathing pure with opiates, have been the means usually employed. Of late years, also, digitalis, which has a positive power of dilating the action of the coronary arteries and increasing the force of the heart, has been prescribed with every appearance of benefit.

That the direction of the arch of the circulation will prevent the rupture of an aneurism, Mr. Hodgson considers is established by the following explanation:

If two sacs exist in the course of the same artery, the aneurism which is caused by the junction of blood into the vessel contains the force of circulation from the lower, much lessens aneurism, or at least it is the lower, much lessens aneurism.—(*On Diseases of Arteries*, p. 143.)

It was this opinion of the celebrated Valsalva, that the utility of a lowering plan of treatment in aneurism, was that merely raised the death of aneurism patients. It was his belief, that the method might be made to such a degree as to be not already very truly such a degree; and he put it forth further with such power and perspicuity, that the treatment he considered as particularly his own. The plan was adopted as it was, devoted to his memory, and was published in the first volume of the *Chirurgia*, one of his two *Historiæ*, and several others, who had heard Valsalva's method, afterwards imitated it in others. Thus, in Morgagni was passing through his hands, in 1726, Morgagni, a physician of the same, is said to have imitated him of Valsalva's plan—also on this subject directing, after Sir. Blandin, p. 1, p. 225.)

After taking away a great deal of blood by venesection, Valsalva used not to diminish the quantity of food gradually, till the patient at length was almost only half a pint of soup in the morning, with a quantity of a pint in the evening, and a very small quantity of wine, mixed with quantity of opium, or with the laudanum. When the patient had been so reduced as to be incapable of getting up at the bed, Valsalva used to give him some anodynes, and the extreme debility then occurred. Valsalva was sure, that some aneurism, that existed, had got well, because every symptom disappeared, and the cure was verified by an opportunity which he had of dissecting the body of a person that had been cured of this disease, and observed that of another aneurism, the artery which had been dilated was found contracted, and in some degree calcified.

Morgagni relates, that the method of treating aneurism is somewhat like the plan which Blandin had used with success, as well as Valsalva, and he is less so in the 28th chapter of the 2d vol. of the *Anatomy of the man*, and in the 2d, cap. 4, of the *Treatise on the Heart and Arteries*, of the other. His title tells us, that in consequence of this instruction, he examined both these works, without finding any thing on the subject. However this may be, he is referred by the latter, that he has seen the greatest effect of the pressure in an aneurism, who had as strong an opinion in front of the horizontal extremity of the circle, in consequence of a sweet-scented in the neck. The patient, after having been bed several times, was confined to his bed, and kept to an extremely low diet. He was allowed to drink only a very small kind of beverage. He took pills consisting of castor oil, and the weight was covered with a sac of aneurism, and which was every now and then well wet with oil. By a perspiration in this treatment, the swelling was reduced to a small hard tubercle, having no pulsation, and a perfect cure ensued.—(*See* *See* *See*, if above by Morgagni, p. 2, p. 170—171.)

Morgagni recommended the application of no water or poultice, but so electrical wrappings; a plan which he represents as being often of itself sufficient to effect a cure. This typical employment of cold applications may be currently and continuously adapted to one patient with Valsalva's practice.

The most interesting and interesting facts in proof of the efficacy of this mode of treatment, were published five years ago by Pelletan. Indeed, upon the whole, I have no hesitation in saying, that I have never read any modern collection of surgical cases, which have appeared in the time of Valsalva, that show with more than Valsalva's, the efficacy of the method of Valsalva. The following extract from a well-written critique on this work will serve to certify the reality of the efficacy of the method of Valsalva. "The lesson in the treatment is to reduce the patient gradually to a state of a degree of weakness as is possible, without immediately endangering life. It is done by absolute rest, a rigorous diet, and bleeding; or, if necessary, by Pelletan adds the external application of ice, or cold and anodyne vapours, &c. The last two

year 1793 and his book was not published until the year 1772.

"Does it ever happen in surgery," says Dr. Hunter, "that when an artery is opened through a vein, a communication, or anastomosis, is afterward kept up between these two vessels? It is easy to conceive how easy, and it is not long since I was convinced almost, that had all the symptoms might be expected, supposing such a union to have actually happened, and such symptoms as anastomosis must be allowed to be very unaccountable. It arose from bleeding, and that of some parts bleeding, when I was about two years ago, and I understood very little anatomy, how I happened to know that took. The vein, at the opening of the artery, and especially the laceration, which was the vein that had been opened, was quite so grossly enlarged, and made gradually to first natural size, at about two inches above and to reach below the elbow. When treated by pressure they did not much about restorable, and light happened, and when a ligature was applied light passed the former, immediately below the affected part. Both when the ligature was made tight, and when it was removed, they shrank, and returned to a small size, while the latter was kept tight above the artery, at the part where the vein had been opened to bleeding. There was a general swelling in the place, and in the direction of the artery, which would have been best stronger than what is natural, and there was a tremendous pain in the vein, which was strongest at the part which had been punctured, and became insupportable at some distance both upwards and downwards." (Phil. Oss. and Inq. vol. 1.)

In the second volume of this work, Dr. Hunter adds some further remarks on the anastomotic parts.

"In the operation of bleeding, the blood is squeezed into the artery through each side of the vein, and there will be three vessels made in these vessels, viz. two in the vein, and one in the artery, and these will be nearly opposite to one another, and to the vessel in the vein. Thus of what all surgeons know has often happened in bleeding, and the injury done the artery is commonly known by the pulsing impetuously of the stream, while it flows from the vein, and by the difficulty of stopping it, when a sufficient quantity is drawn off.

In the first place, we must suppose, that the wound of the skin, and of the adjacent or upper side of the vein, lead up as usual, but that the wound of the artery, and of the adjacent or lower side of the vein, admit upon the wound of the artery more of the venous sanguine, and, by that means, the blood is drawn from the trunk of the artery directly into the trunk of the vein. Secondly, as this supposition may happen, in reality it differs from the venous sanguine, in one circumstance only, viz. the vessel remaining open in the side of the vein, as well as in the side of the artery. The latter circumstance will maintain a great deal of difference in the appearance, in the tendency of the complaint, and in the proper method of treating it; upon which account, the knowledge of such things will be of importance in surgery.

"It will differ in its symptoms from the common species of aneurism, namely, viz. —

The vein will be distended, or become varicose, and a small pale pulsating artery, arising as usual at the extreme down the artery. It will make a beating noise, which will be found to correspond with the pulse of the artery below. The blood of the tumor will be glaucous, or almost entirely fluid, because kept in contact with it. The artery, superadded, will become larger in the vein, and broader at and upon, than it was in the natural state; which will be found, by comparing the size, and the pulse, of the artery, in both states, at these different places. The reason of which I will speak of hereafter, and the effects of ligatures, and of pressure upon the vessels above the tumor and below it, will be what every person may readily conceive, who understands what thing of the nature of arteries and pulse in the living body.

The nature and tendency of such a complaint will be very different from that of the aneurism aneurism. The vein is greatly more every beat, because of the resistance to the arterial blood, and it is retarded by surgery, more so, last beat. The other, is a short noise, comes to a nearly permanent state, and it is not distended, contains no motion, because there is no communicable resistance to the blood that is forced out at the artery.

The proper treatment must, therefore, be very different from that of aneurism, the progress aneurism requiring different assistance, in such, perhaps in any disease, whatever, aneurism, in the other case, I presume it will be best to be avoided.

If such cases do happen, they will, on a whole, be found to differ among themselves, in every little circumstance, and particularly in the shape, &c., of the anastomotic parts. Thus the situation of the vein may be in one only, or in several, and may extend farther higher in one case than in another, &c., according to the manner of branching, and to the state of the veins in different areas. And the direction of the vein may also vary, on account of the size of the artery that is punctured, and of the size of the vein in the artery and in the vein.

Another difference in such cases will arise from the different progress in which the pulse of the artery may be treated or continued with the office of the vein. In one case, the trunk of the vein may keep close to the trunk of the artery, and the very thin stratum of cellular membrane between them may, by means of a thin inflammation and coagulation of the blood, keep its firmness, so it were, solder the two vessels of these vessels together, so that there shall be nothing like a canal going from one to the other; and then the whole operation will be more regular, and more certainly a duration of the vein only. In other instances, the blood that studies from the affected artery, meeting with some difficulty of admission and passage through the vein, may dilate the cellular membrane, between the artery and vein, into a bag, as in a common spontaneous aneurism, and so make a sort of canal between these two vessels. The trunk of the vein will then be removed in some distance from the trunk of the artery, and the bag will be situated chiefly upon the outer side of the vein. The bag may take on an irregular form, from the cellular membrane being more loose and yielding at one place than at another, and from being abnormally bound down by the fibres of the large vessels. And if the bag be very large, especially if it be of an irregular figure, no doubt, evolutions of blood may be formed, as in the common spontaneous aneurism."

As Scarpa correctly observes, a aneurism of any circumstance is possible for the production of an anastomotic vein: 1st, the division in the vein, and that at the artery must be exactly at the same distance; 2d, the nature of continuity to the segments and upper side of the vein must hold, while the vessel in the deeper side of that vessel and the junction in the upper surface of the artery remain open, and anastomosis is necessary that the arterial blood flows greater facility a distance from the artery into the vein, thus is being effected from the artery into the surrounding cellular substance.

If one of these two circumstances be wanting, either because the branching instrument has entered the artery a little obliquely from the vein, or because the vein has not been sufficiently kept to the artery, an amount of the cellular substance between them, the arterial blood must necessarily does not produce the anastomotic vein; or, if it does, the disease is always complicated with effusion of arterial blood into the cellular substance, or with an aneurism and aneurismal vein at the same time. In this case the small anastomotic vein serves as a short canal of communication between the artery and the vein (Med. Facts and Obs. vol. 4, p. 115); two distinct diseases are in fact being formed from the same cause, and placed one after the other, viz. an aneurism and an anastomotic vein. — Scarpa, p. 422, of 2.) The following marks of distinction between aneurism and anastomotic vein are pointed out by the same author: the anastomotic vein always forms a communicating aneurism; aneurism does not always do so. The cellular substance which connects the side of the aneurism does not always move so strongly the progress of the arterial blood as the cause of the vein in. Now, aneurism, therefore, aneurism, aneurism from being communicated at first becomes diffused; extends along the course of the extended artery; enlarges strongly the surrounding parts; contains static pain and inflammation; and the parts are distended with pulsation. On the contrary, the anastomotic vein is always communicated, increases very slowly, does not produce much pain, and, as it increases, it always extends more or less above or below the place where anastomosis

has been torn; and the extension is in proportion to the greater or less force with which the aneurism is thrown from the artery into the vein, and the greater or less resistance made by the vessel situated in the way between the pressure, and according to the pressure or less resistance of vessels communicating with the aneurismal vein. The matter of the aneurism is generally the same vein, though it is sometimes an arterial aneurism, but an arterial aneurism is the case of a Varix, if the disease is recent. In the course of the aneurism is the centre left by the vessel. The vein is less dilated the further it is from the heart, and in general at the distance of two inches and a half from the heart the vessel becomes its natural size. The blood flowing, as has been exhibited, performs like an artery with a beatable pulse, and having some, which is sometimes so great that the patient cannot sleep if he is lying with his head low, and resting on the injured arm. The trunk of the brachial artery, from the axilla down to the place where it has been wounded with the lancet, strikes with extraordinary force. There is no change of colour nor induration of the skin; and the part is painless. The swelling is compressible and yielding; but it returns as soon as the pressure is removed from it. When the arm is kept far above the head, the blood, like the water in a dam, and the drive being stopped when pressure is made on the communication between the artery and vein, so when a slight weight is applied near the axilla. If the disease be complicated with aneurism, a second pulsating tumour will be found lying under the aneurismal vein. (Surgery, p. 424, vol. 2.)

After reading two cases, illustrations of the nature of aneurismal vein, Dr. W. Hunter proceeds to inquire, "Why is the pulse at the wrist so weak, weaker in the dilated arm than in the other? surely the reason is disease of the vein. If the blood can easily escape from the trunk of the artery through into the trunk of the vein, it is natural to think that it will be driven along the extreme branches with less force and in less quantity."

Whereas it is that the artery is enlarged all the way down the arm! I am of opinion, that it is the consequence of the blood passing so rapidly from the artery into the vein, and so much an extension or rupture to all arteries is growing bodies, and on the arteries, at particular parts when the parts themselves increase in their bulk, and at the same time retain a vascular structure. It is well known that the arteries of the human arm reach larger in the time of adolescence. I once saw a fleshy tumour upon the top of a man's head as large nearly as his head; and his temporal and occipital arteries, which fed the tumour, were enlarged in proportion. I have observed the same change in the arteries of children's extremities, &c. so that I should suppose it will be used by us to universally true in fact, and the reason of it is thereby seems evident. (See Med. Obs. and Inq. vol. 2.)

In this aneurism the junction between the vein and the brachial artery, the trunk of which is crossed at a very small angle, that it is almost impossible to see it at this point, without risk of wounding the artery at the same time. The head of the arm indeed is the only position in which the disease is usually noticed. It is easy to conceive, however, that a serious aneurism may happen wherever an artery of a certain character may immediately meet a large vein. Thus, Harvey observes on this, the trunk, superior to the shoulder in humans, and a rule of aneurismal vein, which had been occasioned by a wound of the patient's arm and artery, and that a history of the disease, accompanied with the pathological premonitions, was sent to the Society Royal Academy of Surgery at Paris. "The aneurism swelling, which was as large as two fists, occupied the whole of the arm to a well-developed man, who some years previously had been wounded with a sword in that part of the limb. At a post-mortem, dissection was found necessary, and was performed with success. At the bottom of the rupture, which the communication between the brachial vein and artery was observed. The vein itself was evidently dilated of the vein, the parts of which, adjacent to the rupture, were dilated, especially the lower extremity of the vessel. The patient's arm was rendered flat, like a piece of tape, and adherent to the outside of the vein." (See Med. de Char. N. 2, 3, p. 136.) Sagar,

Trans. Med. Assoc. 3, vol. 2, p. 177.) Two cases are likewise recorded by Mr. Hunter. In one, the disease was caused in the thigh about four inches below Poupart's ligament, by the point of a pointed iron rod, which had passed through the femoral artery and vein, in the same manner, the aneurismal vein was situated in the femur, and was the consequence of a wound in this part with a sword. (See Treatise on the Aneurism of Arteries, p. 108.) Another French case example of aneurismal vein extension under the axilla.

P. Lacroix was wounded with a sword in a ditch, on the skin of his arm, the part of the attachment of the artery-vein junction was divided, the anterior vessels, the brachial artery and vein at a very deep level, and probably plus a portion of the brachial plexus. A good violent hemorrhage took place, followed by syncope. Pressure was applied to the wound, and the patient conveyed to the hospital at Gros-Caillon. The external wound, which was small, did not bleed at all the following evening, but the artery was again opened by a large rupture, which thickened with the aneurism, particularly at its lower part. A positive issue, five that of the passage of a fluid through tortuous muscular tubes, could also be felt more deeply in the direction of the axillary vein. The arm was quite cold, insensible, motionless, and without any pulse even in the axillary artery itself. On the 5th, the tumour was not larger, but its thickness was strange; the superficial vein on the same side was considerably dilated; and the pulsation of the radial and of the arteries of the opposite arm had augmented. A vein in the right arm was opened, and compresses dipped in coagulated vinegar, mixture of arnica, and ice applied to the swelling. It would be superfluous here to detail the diet, bleedings, and other parts of the treatment. On the 6th day, the distal wound was quite healed. On the 10th, the veins of the arm were observed to be swollen, and swelling and warmth were returning in it, though no pulse could yet be felt. The tumour was much smaller, and restricted to a circumscribed place behind the most painful muscle; but the swelling was still present. Hydrogen gas, the nature of the arm and forearm required their power of action. The hand, however, continued insensible, and affected with pecking pains. On the 15th day, the tumour was quite gone; but the healing wound was unhealed, and the hemorrhages were still visible in the veins of the neck and arm. The arm was not at all wounded. On the 16th day, a pulse in the wrist could be slightly felt; the bleeding wound had become less dense; the veins were less turgid, and their pulsation diminished.

A second instance of aneurismal vein, or rather perhaps of a vein of all the veins of the arm, caused by a sword-wound of the axilla, is also recorded by Harvey. He mentions, however, that a pulsation was observable in the most prominent of the enlarged veins. (See Med. de Char. N. 2, 3, p. 241, &c.)

Dr. Harvey of Philadelphia, published a case of aneurismal vein, which is in several respects interesting. A patient was wounded in the leg with a buckshot; and after the cure of the injury, an aneurismal vein was noticed just below the knee; and in a little time the superficial veins of the limb became dilated, and the bounding nodes, characterizing this species of aneurism, could be plainly distinguished. The patient was sent by Dr. Harvey twelve years after the accident; the veins were then considerably distended from the knee up to the groin, all under which later part was actually experienced, and some three situated on the foot and ankle could not be healed by any of the remedies which were tried. The patient was under the care of Drs. Hays and Wistar. The aneurismal distention of the veins of the leg, and the uncertainty of finding out the communication between the artery and vein, led these gentlemen to cut the first of these vessels in the middle of the thigh. Gangrenes soon ensued, and in this state the patient was further weakened by an unexpected hemorrhage from one of the distended veins; and though the wound was secured with a ligature, the bleeding recovered, the patient became more and more emaciated, and at length expired. When the limb was examined after death, the whole of the trunk of the femoral artery was found peripherally dilated; while all the veins of the limb were considerably distended; a bougie could readily be passed from the popliteal into the posterior tibial artery, which participated in the dilatation, and from

this last artery the instrument could be passed into the vein, through a cyst situated on the inside of the leg below the knee.—See *Dever's Elements of Surgery*, vol. 2: p. 218. Philadelphia, 1823.

Professor Harold, Dr. Huxley, Mr. B. Hall, and Dr. Gorman present cases of the numerous forms which assumed malignancy for duration, twenty, and thirty-five years. Several cases are related by Brissaud, Gombault, and Moutier, of a cure having been obtained by means of trepanning. But as this method of cure, if it does not convert, widens the patient to the danger of a complication of the disease with an infection, it ought not to be employed, except in certain cases where the tumor is small, and in almost all patients at an early period of life, and when both of the removal can be satisfactorily converted into the bone.

Two cases are recorded, in which it was necessary to operate in consequence of the disease being joined with aneurism of the artery, and even burning. The case before us, and a negative result took place above and below the aperture in the artery.—*See Park, in Medical Facts and Obs.* vol. 4, p. 111; and *Plowden, in Medical Magazine*, vol. 1, p. 65.

The latter form of the disease, which is particularly noticed by Dr. Hunter, and now by our friend Mr. Hodgson, is readily understood by reflecting that the artery and vein, when positioned together, do not always take exactly a similar as to let the arterial blood have a direct passage into the vein; therefore may be regarded for some distance from an aneurism; so that the blood passes from the artery into the adjacent cellular membrane, where a sac is formed, into which the blood is poured previously to its entrance into the vein.—*See Gibber's Treatise of Surgeries*, vol. 2, p. 125. Philadelphia, 1822.

[illegible]ANALYTICAL DATA: $\text{C}_{10}\text{H}_{10}\text{O}$ 162.14.

This is the form which the late Mr. John Bell, of Edinburgh, applied to a species of acanthium resembling most of the bloody tumours (cancer) sometimes which appear in new-born children, grew to a large size, and ultimately bursting sent a considerable quantity of blood.

Imported introductions of this disease may be traced to writers; though, before the publication of Mr. John Bell's *Principles of Surgery* it was not charged with certainty. That President has recorded a case of this affection for the express purpose of proving that putrefaction is an essential sign of the existence of an abscess.—(*See Canadian Chirurgical Journal*, vol. 1, p. 72.)

[illegible]

This pigment is a complex of active vitamins such as, according to Dr. John Bell, the cellular substance through which these vitamins are absorbed, resembles the bile of a turkey-cock of the substance of the pla-

coils, spleen, or womb. The irritated and intense action of the arteries fills the coils with blood, and from these coils it is reabsorbed by the veins. The size of the swelling is increased by exercise, drinking, emotion of the mind, and by all causes which moderate the circulation.

In this peculiar disease Dujardin regards the organism as being in an anastomotic state; but, besides this circumstance, he says, these extreme transformations in life is a thousand different ways, absorbing spores, and reproducing carries life those which are found in the corpus ciliatum; and he compares the change to increased activity of the capillary circulation. (*Proceedings of Mr. Huxley's work*, 1, 2, p. 203.) It is observed by Mr. Boyce, that most organisms have followed J. B. in believing that this disease is made of a small cellular structure through which the food passes at its course from the surface and the base. However, he has long been one of those who maintain that the organism only an easily extensible of enlarged vessels. (*Ann. Phil. Med. Jour.*, 1838, p. 724)

In the dissection of a pulsating aneurysm of the aorta in a patient who had died after the operation of tying the common artery, Dr. Macchiacchi found the branches of this vessel on the head - degenerated into dilated veins of extreme thinness and transparency, which apparently resulted from the laceration of the blood, as because elongated, contracted, and ultimately moved on themselves, as can be seen by this sample of drawing the structures which constituted this singular aneurysm. They all lay passively, and the larger portion (especially over the carotid) presented black masses of extravasated coagulated blood. (See *Glasgow Medical Journal*, vol. 1, p. 53.) Two cases are given by Pottius, fully contrasting the true nature of the nature of the disease by Dr. Macchiacchi and Mr. Jones. (See *Glasgow Chron.* 3, 2.) Boyer, who saw one of these cases, describes all the arteries of the neck as being dilated, varicose, knotty, and strongly variegated in some places, in others contracted. (Threat. des Mal. Chir. 2, p. 285.) In the aneurysm described by Dr. Macchiacchi some of the cords spoken of by Mr. John Bell were found, as parasymples, as in the spleen; the bulk of the aneurysm was formed almost entirely by enervated dilated arterial trunks, the veins being but one channel from their healthy state. He adds, that these arteries did not appear to communicate more freely than by their ordinary innervations. Some of these communications, as it appears to me, require interpretation by a careful anatomical inspection of the vessels.

In the female subject the menarche began the day after by amenorrhea in some cases a strikingly irregularity, as the following example illustrates. *Ann Venable*, of 8, Maury, in Rome, was born with a tumour on her chin, of the size and shape of a small strawberry, without pain, heat, or discoloration of the skin. As it produced no troubles for some months, however, it excited little interest, particularly as it did not seem to increase with the growth of the child. For the first fifteen years there was but little attention; but about the menstrual period it increased rapidly to double the size, and became more elongated in form. A quantity of red blood was observed to issue from its extremity. This fact, because, indeed because, painful, and sometimes was sufficiently annoying to produce an alarming degree of weakness. Each period of its return was preceded by a violent pain in the head and vertebrae.

Before and after the appointment of these appointees there was no alteration in the size of the cabinet; the only difference was a small rearrangement of the ministerial teams, with an increase of two in the just, his- torical state degree of *Neoliberalism*.

The reviews at length took place, but in unavailability and at irregular periods, without establishing any fixed discharge from the Hospital at the frequency of the examination.

The bracts were not enlarged till a last floral, but did the structure of properly seem to have an arrest toward inclusion on these glands. At—(See *Parsons Clem. Journ.* vol. 5, p. 78, 74.)

As far as any observations external, the true meaning by autoanalysis is a disease with which a surgeon should never interfere; and if it is decided to try any kind of surgery, the only feasible plan is either a complete removal of the disease with a limb, or leave the limb attached which supply the owner with food.

The first is the strict mode of relief, and should be preferred, when not forbidden by the magnitude or situation of the tumour.

In performing such an operation, as Mr. Wardrop remarks, the surgeon should avoid entering into the substance of the tumour; for if this be done, the haemorrhage is violent; whereas, by making the incision beyond the diseased structure, the flow of blood is much more moderate. (*Med. Jour. Trans.* vol. 9, p. 523.) In a few cases pressure may be safely tried; but all attempts to get rid of a true aneurism from spontaneous by external I should think by no means advisable.

"This aneurism," Mr. John Bell observes, "is a true character of active vessels, which will not be cured by opening it; all attempts to obliterate the disease with caustics after a double incision, have proved unsuccessful; nor does the interposition of particular vessels which lead to it affect the patient; the whole group of vessels must be extirpated. In various years, or in moments of individual ardour, or in extraordinary efforts of blood, such as that produced under the scalp from blows upon the temporal artery, or in those enormous protrusions of aneurisms by pulling the hair, and also in the bloody effusions from sores of the head which have a distinct pulsation, the process of cutting up the vessel, aneurism, or arteriole, enables you to obliterate the vessel and perform an easy cure. But in this enlargement of inextinguishable vessels, in the aneurism by anastomosis, the rule is, 'not to cut into, but to cut it out.' These people are bloody, impatient, because they are large, boisterous, painful, covered with sores, and bleeding, like a vessel in the last stage of ulceration, have been led too often to proposed cures, terrible bleeding cauteries, and the mistakes which I have made, while they tend in some measure to explain the nature and consequences of the disease, will remind you of various unhappy cases, where either partial incisions may have been practised, or the patient fell entirely to his fate." (*Principles of Surgery*, vol. 1.)

That Mr. John Bell has comprised in his account of aneurism by anastomosis certain two-thirds called upon nature be assisted, not, indeed, are the differences between this kind of aneurism and some cases in all defined even by the best writers on surgery. To the consideration of these, however, I have alluded in article, in which the method of extirpating particular forms of the disease by means of a ligature will be explained.

The following case, recorded by Mr. Wardrop, affords a valuable illustration of the nature and situation of one form of this disease. A child was born with a very large subcutaneous tumour on the back part of the neck. It was of the form and size of a hen's ordinary egg. The tumour had been daily increasing; and when Mr. Wardrop saw it, two days after birth, the skin had given way, and a profuse hemorrhage had taken place. The swelling was very soft and compressible; when squeezed it yielded like a sponge, and was reducible to one-third of its original size. On removing the pressure, however, the tumour rapidly filled again, and the skin recovered its purple colour. "Considering the immediate situation of the tumour the only chance of saving the infant (says Mr. Wardrop), I removed it as expeditiously as possible, and made the incision of the integuments beyond the boundary of its tumour; aware of the danger of hemorrhage, where such tumours are cut into. No profuse, however, was the bleeding, that though the whole mass was easily removed by a few incisions, it bled freely.

The tumour having been injured by flowing colour of the skin a few of the larger vessels, its entire structure could be accurately examined. Several of the vessels, which, from the thickness of their coats appeared to be rather more of a large size, and there was one sufficiently large to admit a full-sized ligature. This vessel was quite as large as the carotid artery of an adult. The boundaries of the tumour appeared distinct, some healthy cellular membrane, traversed by the blood-vessels, surrounding it. On tracing these vessels to the diseased mass, they penetrated into a spongy structure composed of numerous coils and curls, like a variety of ferns and wires, all of which were filled with the injection, and communicated directly with the ramifications of the vessels. These

cells and fibres had a smooth and polished surface, and in some parts resembled very much the surface of the heart, others crossing them in various directions like the coronary tendons. The opening in the skin, through which the blood had escaped during life, communicated directly with one of the large coils, from which the largest vessel also passed." (*Wardrop's Med. Jour. Trans.* vol. 3, p. 255.)

In the section on Cerebral Aneurisms I have mentioned the cases in which Mr. Travers and Mr. DeGraaf cured aneurisms by anastomosis in the artery tying the branches of the artery. Professor Palmer also cured an aneurism anastomosing location of the chest and neck of the body by taking up the carotid artery. (*See Med. and Phys. Jour.* vol. 6, July, 1822.) These facts prove that aneurisms by anastomosis, like many other diseases, sometimes admit of being cured on the principle of cutting off or lessening the supply of blood to the part affected.

However, surgeons must not be too confident of the efficacy of this to cure the disease, by tying the main artery from which the swelling receives its supply of blood; and the great cause of failure is the impossibility of preventing it, under circumstances, the maintenance of a considerable quantity of blood into the tumour, through the anastomosing vessels. A case is recorded by Hennen, in which he applied a ligature for three days to the carotid artery, and obliterated it; yet the tumour affected seemed to be only temporary, as in a short time the tumour was as large as before. (*See Med. and Phys. Jour.* vol. 18.) In fact, every vessel, artery, and vein around the disease seems to be enlarged and turgid, and the anastomoses are so intricate that no plan of the circumference of the swelling can be imagined which is free from them. Extreme pain was born with two small red marks on the anterior of the right ear. Until the age of twelve years the chief inconveniences were a sensation of itching about the part, occasional bleeding from it, and the greater size of this part of the right ear. The disease soon extended itself over the whole anterior, and to the back and cheeks; and the upper part of the ear became twice as large as natural. Slight, trifling climatic and constitutional changes began to be perceptible in the tumour, which was of a red colour, and covered by a very thin skin. Soon afterwards its accidental rupture of the patient's hat was sufficient to cause copious hemorrhages, which were difficult to suppress, and at the same time that they produced great weakness, caused a temporary diminution of the tumour and its pulsation. At length the disease began to raise up the scalp for the distance of an inch around the most anterior, and the hemorrhages to be more frequent and abundant. Pressure was next applied to the frequent, carotid, and occipital arteries; but as the patient could not endure it, the first two of these vessels were tied, the only benefit from which was a slight diminution in the pulsation and bulk of the swelling. This treatment did not prevent the return of hemorrhages, and therefore forty-three days after the first operation a ligature was applied to the occipital artery, which was found to be equally inefficient. As the disease continued to make progress, the patient entered the Hôpital St. Louis, on the 9th of April, 1818. Dr. Dupuytren tried what effect tying the trunk of the carotid artery would produce on the swelling. As soon as the ligature was applied, the throbbing ceased, and the tumour underwent a quick and considerable diminution. On the fifth day, slight impressions and continuance of the diseased part of the ear were again perceptible, though the swelling had diminished considerably. An attempt was now made to compress the tumour by covering it with plaster of Paris, a plan which was somewhat painful, though it lessened the size of the tumour. After being six days in the hospital, the patient was discharged, at which period the tumour was diminished one-third; the throbbings had returned, but no unpleasant noises continued to affect the ear. (*See Anecdotes* of Mr. Hennen's work, t. 2, p. 238.)

An infant, six weeks old, was brought to Mr. Wardrop, on account of an aneurism by anastomosis (a subcutaneous tumour) of a very arterial size, situated on the left cheek. The base of the tumour extended from the temple to beyond the angle of the jaw, completely enveloping the cartilage of the ear. At its upper part there was an ulcer, about three lines in diameter, presenting a disgusting appearance. The tumour was

[illegible]

ANTHRAX (anthrax, a burning coal). See **LOCKSMITH**.
ANTHONY'S PILL (see **ANTHONY'S PILLS**).
(Dissolve Anthrax and some Phosphate Salts). In all cases where it is desirable to increase the secretions in general, and those of the kidneys, skin, and alimentary canal, in particular, it is proper to have recourse to antithyroid remedies. In the administration of these fluids and its ingredients, and in that of the greater regularity of organs of the importance in the system, antithyroid should be exhibited. For an adult, from two to five grains of pure anthrax may be ordered, and the dose, if possible, may be repeated three or five times a day. In order to increase the action on the bowels, it is desirably combined with castor oil.

Of late, doctors have argued concerning the efficacy of amniocentesis powder. Dr. Edmunds having prescribed it this is the dose of 100 cc. apparently without any effect. Mr. R. Phillips has suggested to explain the circumstances by the preparation of amniocentesis being the powder, which is known to be inert.—*See Journal of Pharmacy for Dec. 1971. Pharmacologia by Dr. Paris, a M.C. vol. 6, no. 5, 1971.*

ANTHOSIUM MURIATUM, (Warrior of Auto-
momy.) Employed as a rivulet.

ANTIMONI SULFURETUM PRÆCIPITATUM.
An ingredient in the compound colicid pill, and before prescribed in any other form.

ANTIMONIUM TARTARIZATUM. (*Emetic Tar-*
tar.) Of this useful medicine, the best preparation is
the vitriol antini tart. every half ounce of which
contains one grain of antini tart. Tartarized ant-

many, in the case of gr. 1, will, if the sun is kept warm, produce a staphylinus; gr. 2 will produce some staph. dark and sweating afterwards; and gr. 3 will generally make something, these perhaps, and finally pupation. In very moist soils, as gr. 3, 10 or 12, combined with sand and sugar-cane, it will be an exception. As Mr. Perry justly remarks it is decidedly the most profitable, and the best method of all the other experiments, and the quantity would probably have not failed to equal, were all the other combinations of interest discarded from the pharmacopoeia.—(See Pharmacopoeia by Dr. Ross, vol. 2, p. 67, 68, 69.)

Terminated latency is sometimes followed with further spreading, especially if the initiating release and possible of the target tissue, thereby re-initiating the infection. (See Discussion.)

ANTHRAX. *Bacillus* ϕ . This clostrid is fatal in a variety of diseases. Sometimes the virulence is high, inflammation, and necrosis are accompanied by systemic effects of toxins; at other times, in consequence of inflammation at other centers, it is the seat of various endocarditis, polypl, and flaps. Even the toxic portion of the anthrax are occasionally effected with mucous abscesses. Sometimes it contains enormous fungus, and it is even described that insects may be generated there, and cause. As heavy virus, very afflicting man.

49142011658 52, 51X08, 520 000.

Inflammation of the middle-ear, being, in the ordinary cases, produced by an extraordinary secretion of mucus, within which the collected fluid being confined, the body partakes of the cavity being expanded to a surprising degree. This disease, says Robert, is sometimes accounted for a blow to the eardrum, or to the tibia, or the projection of one of the teeth into the antrum. But in general, the cause takes place unperceived by any of these causes, and without there being the least ground for suspecting what has given rise to the disorder. It is remarked, however, that soldiers some of whom walk in the streets are soon seized with young abscesses of three puncta sort by Boyer, the abscess was not more than two—(Frost, *see Med. Clin.* t. 6, p. 129.) As Mr. Hunter has noticed, whether the obtaining of the fluid leading to the nose, be a cause or only an effect of the disease, is not easily determined; but from some of the symptoms, there is great reason to suppose it an antecedent. "If it be a cause, we may suppose that the natural expanse of these cavities, accumulated, mucus, and produces inflammation for its own sake, in the same manner as an obstruction to the passage of the urine through the ducts of nature produces an abscess of the urinary sac."—(See Boyer's *Natural Hist. of the Urine*, p. 174, ed. 3.) The most interesting example of the effects of the impediment of mucus in the antrum, is that recorded by Delius; a boy, between seven and eight years of age, was observed to have at the base of the ascending process of the upper jawbone, on the left side, a small, very hard tumour of the size of a nut. As it gave no pain, and did not appear to increase, his parents did not consider him any concern about it. When he was about sixteen, however, the swelling began to increase, and to be somewhat painful. Before he was sixteen, an inflammation was so considerable that the flow of the saliva was caused up by it, the eye thrown upwards, the palpitating which ceased; the neck of the patient passed down in the form of a tumour; and the nasal airway closed. Below the orbit there took place a collection of pus, which the nose was directed towards the opposite side of the face, and the skin at the upper part of the tumour, below the lower orbit, was of a purple red colour and threatening to burst. The upper lip was drawn upwards, and bent in all the places as the left side were observed to project much farther than those on the opposite side of the face, and at this point came the tumour at the very surface of the nostril was perceptible. The patient spoke and breathed with great difficulty; he slept uneasily, and his countenance was painful. The case was first suggested by Delius, Schaefer, Pottius, and Boyer, to be a fungus of the antrum, and an operation was considered suitable. In proceeding to this measure, the first thing which attracted the notice of Delius was a sort of tumour in the situation of the great brain of the upper lip; a circumstance which led him to give suspicion of the

case being a fungus, though he expected that, on making an opening, merely a small quantity of wheaten matter might escape, affecting at first no inflammation. In this place, however, he determined to make an incision along the alveolar process, whereby a large quantity of a glutinous substance like lymph, or what is called a mass of fungus, was discharged. A probe was now introduced, with which Dubois could feel a white equal in extent to the thickness of the tumour, and in moving the instrument about, with the view of ascertaining whether any fungus was present, it struck against a hard substance, which felt like one of the lower teeth, near the opening that had been made. Five days after the first operation, Dubois exhibited two tumours and one granule, and then removed the corresponding part of the alveolar process. As the incision was not profound, the wound was soon filled with drainage, which in two days came away, and dried before it closed, with hardly any loss of the vitality of the cavity. At its upper part, he perceived a white spot, which he supposed was just left on healing it with a probe, it thrust out to be a tooth, which was then extracted, to show which was the bone was irregular. The rest of the treatment merely consisted in drying the cavity, and applying caustic drugges. It seems not unlike all the better cases I have seen, but the swelling of the cheek and pain, and the displacement of the nose, with exception. In the course of another year and a half, however, every vestige of debility was entirely restored. (*Dubois, Archives de la Faculté de Médecine*, 12, No. 3.)

With respect to the treatment of collections of matter in the antrum, by means of incisions, through into that cavity through the natural opening at it, while the head is inclined to the opposite side, for the purpose of facilitating the escape of the collected fluid, as proposed by Jourd'ain in 1765 (*Mém. de l'Acad. de Chir.*, t. 4, p. 357), Deschamps and Boyer are of opinion that the method is objectionable, not only because it is difficult to find the aperture, which, on the disease being an upward swelling, is probably obliterated, but also because the thickness of the mucous membrane would make it impossible for the surgeon to push it out with injections. Hence, Boyer approves of the practice of opening the manner in an oblique position, and so as not to afford for the discharge of the pus. (*Deschamps, Traité des Maladies des Parties Nées de la tête*, t. 3, p. 331, 332, 333, 334; *Boyer, Traité des Acad. Chir.*, t. 6, p. 145, 146, 147, 148.) Indeed, that Deschamps's proposal was attended with too much difficulty for common practice, was the sentence long ago pronounced upon it by a treasurer of the Royal Academy of Surgeons in France, maintained for the express purpose of injecting into the mouth of the suggestion. The method of making an opening into the antrum, will be considered in the sequel of this article. As a general rule, I may here remark, that except when a fungus or fungus begins to be extruded, or a foreign body to be extruded from the antrum, it is quite unnecessary to remove any part of the alveolar process, or cut away any of the bony parties of the antrum; the drawing at one of the teeth situated below this cavity, and making a perforation in this situation, being the only kind of opening required. This aperture may be enlarged as long as necessary, by the introduction of a piece of elastic gum catheter, which is to be fastened to the adjacent teeth, and through which the surgeon to the antrum may escape, or incision be injected. (*Deschamps, Traité des Mal. des Parties Nées de la tête*, t. 3, p. 331.) However, as Hister remarks, if the height of the tumour has destroyed, even though the case be merely a collection of mucus or pus, an opening may be made to the inside of the lip, but not accurate at the difficulty of maintaining such an aperture. It will however be the purpose of drawing out of the mouth. (*Waring, Hist. of the Teeth*, p. 176, et. 2.)

If all the dissections, however, are by the most accurate. Yarned there on the cheek, and necessary affections of the adjacent parts, and especially of the pterygoid, extending along the nostril, capable of being cut away, and, above all things, the teeth, may bring on inflammation and suppuration within the cavity of the upper jawbone. The first operation is removal of any part of the alveolar process, and particularly of those should be a vigorous tooth at the point of the jaw. Each part, however, extends more

into the ribs, than that usually does which arises from a decayed tooth: it also affects, more or less, the eye, the orbit, and the situation of the frontal sinus. (*Waring, Hist. of the Teeth*, p. 175, et. 2.) But even these symptoms are insufficient to characterize the disease, the nature of which is not invariably affected till a much later period. The complaint is, in general, of much longer duration than was formerly supposed, and on a closer look, and its violence is more or less, and, at last, a hard tumour is perceptible below the cheekbone. By degrees the swelling extends over the whole cheek; but it afterward flows in a point, and leaves a very irregular, hard, and, which may be felt above the back of the teeth. The symptoms is accompanied with redness, and sometimes with inflammation and suppuration of the adjacent parts. It is not uncommon, also, for the outward sinuses to participate with that within the antrum.

The characteristic direction of the tumour, however, does not occur in all cases. There are instances in which the matter makes its way towards the palate, causing the bones of this part to swell, and at length rendering them carious, unless directly procured to give. There are other cases in which the matter escapes between the lips and cheeks of the mouth. Lastly, there are certain examples, in which the matter formed in the antrum makes its exit at the nostril of the alveolar. When the patient is lying with his head on the opposite side to a low position. If this mode of exit should be frequently repeated, it prevents the tumour both from pointing externally and breaking, as it would, do if the patient were could not do so. But this evacuation of pus from the antrum is not very common; for, according to Mr. Adams, the opening between the nostrils and cavity of the antrum is generally stopped up. He even seems inclined to think, as I have already observed, that the disease may sometimes be occasioned by the imperious state of the opening, in consequence of which the natural mode of the antrum collects in such quantity, as to irritate and inflame the membrane with which it is in contact, just as an obstruction in the ducts of the pancreas the passage of the fluids into the nose, and causes an abscess in the lacrymal sac. This is a point, however, on which even Mr. Adams would not venture to speak with certainty; for it is by no means impossible that the suppurative stage of the opening is rather an effect than the cause of the disease, since inflammation in the antrum is often manifestly produced by causes not at all distant from, and since the opening in question is not invariably closed.

Abscesses in the antrum require a free exit for their contents, and if the surgeon neglects to procure such opening, the bones become more and more destroyed and pushed out, and finally carious. When this happens, the plan makes its suggestion, either towards the orbit, the alveoli, the palate, or, as is mostly the case, towards the cheek. The matter having thus made a way for its escape, the disease now becomes stationary.

In all cases, whether the pus be simply confined to the antrum, or whether the case be complicated with a general affection of the bones, the principal indication is to discharge the matter.

The ancients seem to have known very little about the treatment of Abscesses of the antrum. Boerhaave, an English manuscript, is reported to be the first proposer of a plan for curing abscesses of this cavity. (*Antropologia Nova*, London, 1725.) However, M. Moreau was much earlier in proposing, with the same intention, the extraction of one or more of the teeth, in order that the matter might have an opening for its escape through the sockets. This plan may be compared with success. The gum frequently has a tendency to make its way externally towards the teeth; it often affects their fangs; and, after their extraction, the whole of the alveoli is soon to escape through the sockets. But this very simple plan will not suffice for all cases; as there are numerous instances in which there is its continuation between the alveoli and the antrum.

Drake, and perhaps better than Cooper, was of the opinion of the insufficiency of M. Moreau's method, and hence they proposed making a perforation through the socket into the antrum with an awl, for the purpose of letting out the matter, and injecting into the cavity with fluids as were judged proper.

M. Jourd'ain recommended in the French Academy of Surgery, the insertion of detached bones into the

through opening of the nostrils, by means of a curved pipe introduced into the nostril; but, without dwelling upon the difficulty of effecting this method in practice, especially where the opening is closed, many must on the authority of the French surgeons themselves, that the more employed use of operations is not in those cases an efficient mode of treatment.—(See *Brit. Med. Journ.* 1851, p. 283.)

In the treatment of abscesses of the nostrils, the extraction of bone is never tried, and the perforation of the alveoli, being generally essential steps, we must consider what steps ought to be taken out in preference to others.

A corner, or even a more forward abutting, of any parietal bone, in general, tends to develop the disease. But if at the teeth should be sound, which is not often the case, writers direct us to lay each of these firmly, and to extract that which gives most pain on this head done. When no information can be thus obtained, great consideration ought to guide us.

All the greater teeth, except the first, correspond with the nostrils. They open sometimes beyond into the cavity, and the fangs are only covered by the parietal maxillae. The bony lamina which separates the nostrils from the alveoli, is very thin towards the back part of the upper jaw. Hence, when the disease is in that power, it is best to extract the third or fourth grinder, as in this situation the alveoli can be more easily performed. Though, in general, the first grinder and canine teeth do not communicate with the nostrils, their distal approach on each side of it, and from their work on covering very readily be extended into that cavity.

When one or more teeth are carious, they should be removed, because they are both noxious and painful. The matter frequently makes its escape as soon as a diaphragm is destroyed, in consequence of the fang having extended into the nostrils, or even as a consequence of its bulging away with it a piece of the thin partition between it and the cavity. Perhaps a discharge may follow from the partition itself being carious. If the opening thus produced be sufficiently large to allow the matter to escape, the operation is already completed. But as it can easily be enlarged, it ought always to be so when there is the least suspicion of its being one-sight. However, when the pus makes its appearance after a tooth is extracted, the alveoli must be opened or enlarged by a pointed instrument in the direction of the alveoli. Some use a small spear or awl, others a graver for this purpose.

The patient should sit on the ground in a slanting light, resting his head on the surgeon's knee, who is so at least his eye. Immediately the instrument has reached the cavity, it is to be withdrawn. The entrance into the nostril is easily known by the cessation of resistance. After the matter is discharged, surgeons advise the opening to be closed with a wooden stopper, in order to prevent the entrance of extraneous substances.

The stopper is to be taken out several times a day to allow the air to escape. This plan most depends the patient affected to discontinue the suppuration, and restore their natural state. Sometimes, however, the pus continues to be discharged for a long time after the operation, without any change occurring in regard to its quality or quantity. In such instances, the cure may often be accelerated by employing syringes of bread and water, lime-water, or a solution of the sulphate of zinc.

Some surgeons prefer a silver canula, or a piece of glass pipe either, instead of the stopper, as it can always be left pervious except at night. The canula on round, where the extraction of a tooth and the perforation of the bottom of the nostrils were the means of curing abscesses of that cavity, are very rare.—(See *Parvelli's Medical Cases*, No. 5; *Good's Cases*, p. 18, note; *Edinb. Med. Journ.*, 1851, p. 10.)

If no coming were made in the nostrils, the matter would become so very viscid towards the front of the cavity, which is very thin; sometimes towards the mouth; and fistulous openings and canals would inevitably follow.

When the bones are diseased, the alveoli plug will not accomplish what must be effected by the use of bone substitute. A probe will generally guide us to detect caries in the nostrils. The first cause and obvious appearance of the disease, when there is little doubt that the bone is diseased, and in proportion to the

bones free themselves of any dead portions, the discharge has less smell and its continuance becomes thicker.

When there are loose pieces of dead bone or other foreign bodies to be extracted, it is requisite to make a larger opening in the nostrils than can be obtained at its lower part. Instances also occur where patients have lost all the growing teeth and the sockets are given softness, so that a perforation from below cannot be effected. These practitioners object to carrying a sound tooth. In these circumstances, it has been advised to make a perforation in the nostrils above the alveoli process: a method first suggested by Lennet. It consists in making a transverse incision below the nasal process and above the root of the third grinder. Then the gum and pericosteum are divided and the bone exposed. A perforating instrument is to be introduced into the middle of this incision, and the opening in the nostril made as large as possible.—(See *M. de l'Acad. de Chir.* t. 4, p. 251; *Good's Obs.* append. p. 125.) There are some extensive suppurations of the nostrils where it is absolutely necessary to expose a great part of the wall of the bone, and to lay open the nasal process which are united, as it were, in the alveoli. A small incision may sometimes be advantageously applied to the nasal process of the superior maxillary bone.

Surgeons formerly treated cancerous affections of the nostrils in the most stupid and unscientific way, introducing severs through the cavity, and then having recourse to the actual cautery. The moderns, however, are not much inclined to adopt this sort of practice. It is now known, that the destruction of a dead portion of bone, is either before the process of epithelization, is healthy, or not entirely the work of nature, in which the alveoli are a very delicate part. Indeed, he should limit his interference to providing the ingress of matter, maintaining strict cleanliness, and removing the dead pieces of bone as soon as they become loose. But it is to be understood, that extraneous bodies present themselves, in which the dead portions of bone are so intense of separation, and are obliged to be withdrawn at the surrounding living bone, that an attempt may properly be made to cut them away.

SOURCES OF THE ANTRUM.

Boeck, Barthez, Desault, Abernethy, Weiskind, and others, have recorded cases of polypus, fungous, and cancerous diseases of the nostrils, and examples of this cavity being affected with exostoses.

The existence of any ordinary fleshy tumour in the nostrils, while it is an incipient one, certainly tends to conceal its existence; but such a disease rarely occurs without being accompanied with some affection of the neighbouring parts; and hence, as previously may possibly be ascertained before it has attained such a size as to have altered, in a serious degree, the natural shape of the nostrils. This information may be acquired, by examining whether any of the teeth become loose, or have spontaneously fallen out; whether the alveoli process be diseased, and whether there are any fungous excrescences making their appearance at the sockets; whether there is any unusual bleeding from one side of the nose; any carcinoma tumour at the side of the nostril, or towards the great angle of the eye. When the swelling, however, has attained a certain size, the bony portions of the nostril always protrude, unless the body of the tumour should be situated in the nostril, and only the root in the nostril. This case, however, is very uncommon.

As soon as a tumour is certainly known to exist in the nostrils, the front part of the cavity should be opened, without waiting till the disease makes further progress. In a few instances, indeed, we may avail ourselves of the opening which is now and then found in the alveoli process, and enlarge it sufficiently to allow the matter to be withdrawn. If the front of the nostril were freely opened, it would in general be better to cut away the disease in its interior.

A swelling of the process of the nostrils is considered of an abscess, or a carcinoma, though in the cavity, may lead to its rupture through an enlargement of the bones, or an exostosis. The symptoms of the first two affections have been already detailed. One sign of an exostosis, besides the absence of the symptoms characterizing an abscess of a sinus, is

outlet of the external surface of an abscess after delivery should be an examination of all the natural outlets of the rectum.

The point in which the extremity of the rectum, or the anus, ought to be, may be entirely or partly shut up by a contraction of fleshy adhesions. In other instances, no swelling of the membrane can be formed, as the skin retains its natural colour, and the whole mass between the parts of protraction and the os coccygis, without being upon elevated in one place than another. In these cases, the intestine sometimes terminates in air, or *per-ædæ-mat*, about as each sigmoid flexure from the ordinary situation of the anus.—(See *British Medical Journal*, N. S., Vol. 6.) Sometimes it does not descend lower than the upper part of the rectum, sometimes it opens into the bladder or vagina. Dr. Palmer dissected a man where the colon, after reaching the flexure of the left kidney, began, as it descended, to form a sigmoid flexure, and previously to its arrival at the os coccygis of the left ilium, made a valvular turn to the right; and crossing the psoas muscle, reached the peritoneum of the rectum, where it terminated, instead of at entering the pelvis. With this malformation was combined an imperforate vesicular urethra, and other considerable deviations of the genital organs from their natural situation.—(See *Medical-Chir. Journal*, vol. 1, Nov. Lond. 1818.)

Sometimes the *colon* terminates in a way and the rectum is entirely deficient.—(See *Burgard*, in *Journ. de M. d. l. 1, 66*.) Instances are also upon record where the rectum opened into the uterus.—(See *Nov. 1719*, p. 772; *Hist. de l'Acad. Royale des Sciences*, 1720, p. 113; *Recherches de M. de Willebrord*, 1760, pp. 15; 1763, No. 13; *Recherches de M. de Willebrord*, 1760, pp. 15; 1763, No. 13; *Recherches de M. de Willebrord*, 1760, pp. 15; 1763, No. 13.)

When a surgeon is consulted to treat not less much time as dissection; for if a speedy operation be not made for the fever, the patient will certainly very soon perish, with symptoms similar to those of a strangulated hernia. Mr. C. Hathorn claims it, however, advantages not to operate till the expiration of from twenty-four to sixty hours after birth, as within this period no great inconvenience will arise, and the distention of the rectum with mucus is a guide to the surgeon in making the incision.—(See *Doc. in Surgery*, vol. 2.) After ascertaining the complaint, which is an easy matter, the surgeon should endeavour to learn whether the anus is really shut by a transverse or fleshy adhesion, or whether the anus is altogether missing, in consequence of the fever, or from the cavity of the gut being obliterated or the rectum not extending sufficiently far down.

When a membrane or production of the skin closes the opening of the rectum, the part producing the obstruction is somewhat different in colour from the surrounding integuments. Its form is of a purple or livid hue, in consequence of the arrestedness of the mucus on its inner surface. The membrane, propelled downwards by the visceræ above, forms a small reddish prominence, which yields like dough to the pressure of the finger; but immediately projects again when the pressure is removed. When a fleshy adhesion closes the intestine, the circumstance is different to this, if the part protrude, as is generally the case. The finger feels greater hardness and resistance than when placed in a mere membrane, and the livid colour of the membrane caused by mucus through the obstructing adhesion.

These last signs alone are enough to convince the surgeon of the necessity of the operation; for they do not clearly show whether the intestine descends as far as it ought in order to form a proper kind of anus. Complete information to this point can only be acquired after the membrane or adhesion has been divided, or else after the child's death, when the operation has proved ineffective. Though there be no death to denote where the same ought to be situated, and no degree of protrusion, yielding like soft dough to the pressure of the finger and rising again when such pressure is removed; yet it may happen, especially on one being conducted immediately after the child is born, that notwithstanding the absence of such symptoms, during the presence of the mucus, and the natural colour of the intestine, as far as where the tube ought to be, the gut may extend into a cavity as far as the membrane or adhesion closing it.

When the anus is completely covered with skin, and its place indicated by a premature protrusion from the con-

tests of the rectum, we have only to make an opening with a knife, sufficient to let out the mucus. Later, however, a circular incision in the membrane, or membrane, is sufficient. A small bit of oil is afterwards to be introduced, in order to keep the opening from closing. If the anus be only partly closed by a membrane, the opening may be dilated with tents or bougies; but if the aperture be very small, it is preferable to use the bistoury for its enlargement.

When an external appearance denotes where the extremity of the anus ought to be, the case is much more serious and embarrassing; and this, whether the intestine be stopped up by a fleshy adhesion or the obliteration of its apices, or whether a part of the gut be wanting.

However, it is the surgeon's duty to do every thing in his power to effect relief. For this purpose, an incision an inch longer rather more is to be made in the situation where the anus ought to be, and the wound is to be carried several more deeply in the external rectum of the intestine. The cuts are to be made directly upwards, not at the side of the penis, for the vagina or bladder might thus be wounded. On the contrary, the operator should yet backwards, along the convexity of the os coccygis, where there is no danger of wounding any part of importance. In all cases of this kind the surgeon's finger is the best director. The operator, guided by the index finger of the left hand, is to insert it into the intestine within the os coccygis, is to depend on the direction above recommended, until he reaches the feces, or has cut as far as he can reach with his finger. If he should fail in finding the mucus, as I have said, unavailingly follow, one more attempt might be made by introducing, upon the finger, a smaller and firmer, in the direction last indicated, to reach the rectum without danger to other parts, viz. upwards and backwards. The contents of the rectum may be let out in the perineum, and secured there by lint, which is used as a guide for the finger. In some observations on this subject, addressed to the Medical and Chirurgical Society by Mr. Charles Hathorn, he recommends an elastic gum catheter to be substituted for the finger after a week, and when the tube can be disposed with a sponge tent or piece of bougie, as in which 12 and 14 hours.—(See also *Doc. in Surgery*, vol. 2, 1808.)

In a very interesting case, recorded in *Lancet*, it was surgical history, the importance of the case was not discovered till the evening of the 11th day from the child's birth, when through and communications had come out. M. Wood found the abdomen preternaturally hard, and painful when handled, and when examined, and great depression of strength proved. Next day, he introduced a large barrel a few inches into the depth of the os coccygis of an inch without finding the mucus. The patient was then turned to the depth of two inches without effect. With a pharyngeal, however, he soon succeeded in passing the rectum; and a glyster was administered, which brought away some mucus. Under the use of clisters and tents the child soon recovered.

In such proceedings many infants have been preserved, which would otherwise have been devoted to certain death. Hathorn, La Motte, Blandin, M. Crotier, Hathorn, and others have successfully adopted the practice. Mr. B. did not with freedom, in which the intestine was very distant from the perineum, and he was so successful as to form a fistula, which yielded its contents freely to the finger, but he found it exceedingly difficult to keep the passage sufficiently permanent. As soon as he removed the help of his hand, and other kinds of tents, used the necessary assistance, with a degree of continuance speedily followed, that the evacuation of the rectum not being so very difficult for a long while afterwards. He employed, at different times, tents made of sponge, gutta serena, and other substances, which went as long as was needed. But they always produced no effect, and he argued that it was impossible to persevere in their use.

Tents of very soft lint, dipped in oil, or some of the same kind, cause less irritation than those composed of less elastic materials.

Though keeping the moving clister was some service and may to some extent have had no opportunity of doing more or less, it is far otherwise in practice. Mr. B. did not mean to, that he never met with any disease that gave rise to such a state of

embarrassed as he experienced in the two cases of the wart which occurred in his practice. Although in both instances he made the openings at first sufficiently large, it was only by very anxious attention for eight or ten weeks, that the necessity for another operation, and even repeated operations, was prevented. When only the skin has been divided, the rest of the treatment is, of course, more simple; for then nothing more is requisite than keeping a piece of wax for a few days in the opening made with the knife. But upon the extremity of the rectum as in a certain instance, though the anus generally hopes to effect a cure, after having succeeded at going, too, in the previous anal, yet the treatment after the operation will always demand for a long while a great deal of attention and care on the part of the surgeon. In a highly interesting example, recorded by Mr. Milne, of Montreal, such was the tendency or closure of the new opening, that he was obliged to repeat the operation. Mr. Vaux before the child was eight months old.—(*See Med. Rev., Journ. No. 48, p. 62*.) Notwithstanding all these operations, and another one of some kind and three-quarters' duration, performed several years afterward, the stricture of an almost constricted canal is said to be a cartilaginous, the power of the sphincter was perfect. The efficacy of surgery only to be considered as in some measure proportioned to the depth of the stricture involved. In a case like that recorded by Dr. Palmer, in which I have above adverted, the laxity of any attempt to disengage the fibres by an operation at the anal side of the stricture is, as I have said, almost—(*Medico-Chir. Journ. vol. 1, p. 194.*)

Consequently, while the *area* appears peritoneal and well drained, actually under the same symptoms as if there were no *area* at all. The reason of this depends upon the formation being occasionally closed by a membranous partition extended more or less upwards, above the aperture of the ureth. (Conrad, *Nocturnal Incontinence*, p. 147; of John Wombey, in *Edin. Med. and Surg. Journal*, April, 1811; and Cases in Hirschman's *Obs. in Surgery*, of 2), and sometimes the symptoms are owing to the formation of the gut in a cleft sense. This erroneous formation may always be suspected upon an infant, whose *area* is externally open, does not void any excrement for two or three days after its birth, and especially when urgent symptoms arise, such as swelling of the belly, vomiting, &c. We are now to endeavour to ascertain whether the reason is imperforation above the *area*, by attempting to inject glysters or to introduce a probe. If the gut is straight there is nothing to be done but leaving prepared to the method described above, and forming a communication by means of a bistury passed on the finger, or else with a pharyngotome. If the obstacle should only consist of a transverse membrane, the operation will be easy and its success highly probable. But if there should be a *diaphragm* or obstruction of the *aperture*, the case is actually more severe.

In the case recorded by Mr. Wingo, the diarrhoea began was felt by the father about six weeks from the birth of the babe. It was paired with a gonorrhoea which was followed by a hydrocoele trosser, and afterward by a fungus of larger dimensions. On withdrawing the latter, much mucus was found with some blood, and continued to be frequently discharged. In a week, however, the opening closed, and a fresh patient was made, which was unattended by the foregoing introduction of fungus. The child provided tolerably well until the end of another week, when the passage was again much contracted and the abdomen proportionately distended. On the 20th day from birth, a full-sized penis was used for restoring the opening, which, however, again had a tendency to close, the man afterwards being obliged to introduce twice a day bougies, which were introduced in size until a constant course of dilations would be required. The boy now rapidly improved, and every sign of a gonorrhoea was eradicated, but because of the oscurity the case, and at the end of six months the little patient died hectic. (*Am. Edin. Med. and Surg. Journ.*, vol. 17.)

When the skin is dissected, the intestine sometimes opens into the vagina or bladder. (Dumas, in *Revue P. l'analyse de la Soc. de Med. t. 3, No. 13, 1840*; *Rapport du Thénar* et la Soc. Philom. vol. 1, p. 145. *Murres, Mem. de la Soc. des sciences*, 1811, 1784. *Act. Med. et vol. 6, Obs. 34, vol. 9, (Obs. 1).* *Kloster, in Marrocco's Jour. f. d. Chir. d. 1.*

547. *Obs. Bot. Dered. V, No. 2.* The first case is the least dangerous of such malapropisms. The intestines may also be divided at two places at the same time, viz. at the nasal place, so as to form a proper suture more or less perfect; and also in the vagina.

If these two openings would be large enough for the easy evacuation of the excrement, nothing can be done on tender 20 days, far enough visiting the Jews (though the vagina is a most magnificent instrument), yet there is an efficient means of avoiding the opening of the intestine in this situation, nor could one be devised which would not seriously compromise the infant.

But when the two openings are exceedingly small, and the active ingredients (anhydrous calcium chloride, for example) are not in the form of a fine powder, the opening of the straw must be filled by means of a different device. If this method should not avail, the knife must be employed, and the wound dressed as already explained.

For the same part the intestine has only one opening in the vagina. In this circumstance, we see the intestine in which the feces have to exit at all, we must make an incision in that place where the same might be necessary. The natural course of the feces being opened in this opening, which in such a case is not at all painful, because less muscular wall pass out of the vagina, and of course the intestine will be discharged. 6) the introduction of a tube into the lower strait, the communication between the rectum and vagina might possibly be destroyed, and a better cure accomplished. The opening between the intestine and vagina may also be too small for the easy evacuation of the feces, and recti expose the infant to the same sort of dangerous symptoms as would occur if the rectum had no opening at all.

In male infants, the prepuce sometimes opens into the bladder, and in this circumstance there is generally no pain. The fluid is easily known by the mucus, being streaked with the urine, which acquires a thick greenish appearance, and is voided almost continually enough in small quantities. Only the most fluid part of the mucus is in this discharged. The thicker part not getting from the urethra into the bladder, nor from the bladder into the urethra, greatly diminishes the irritation and bladder, and produces the same symptoms as take place in cases of total impaction. Hence, without the speedy interference of art to keep it from capable of giving vent to the urine, with which the urinary organs cannot remain obstructed the infant will inevitably die. This case must, therefore, be treated like the foregoing examples. Though we can hardly hope to prevent altogether the inconvenient urination from the prepuce opening into the bladder, we may even a few passages will not completely hinder the urine from following the other course; yet we shall thus avert the cold and very bad chances of preservation, and the only one which its situation will allow.

In cases in which an outlet for the feces cannot be obtained by any of the methods pointed out above, it has been proposed by Littré to make an opening above one of the pikes, find out a portion of intestine, open it, fix it in this situation with a few stitches, and thus form an artificial anus. Substituting this very un-pleasant with one case in which the proceeding had been actually done, viz. the example where Ducrest, a French naval surgeon, operated. This gentleman told us the accident at the lower part of the left iliac region, and having opened the sigmoid flexure of the colon, he fixed it near the navel. "The child was saved by the formation of an artificial anus; but at the age of twenty-five months it continued to be troubled with a sort of prolapsus of the lining of the bowel." (See *Richard's Encyclopedia for Nov. 1864*, 2, 4, No. 19; and *Substit. Med. Dictionary*, 1, 2, 4, 266, 1, 10.)

An instance has been published by Mr. Price, in which he made an opening in the osseous part of the sigmoid flexure, in a lady, who, in consequence of a serious disease of the osseous part, was afflicted with an enormous and painful distention of the intestine, causing the patient to survive the operation nearly sixteen months, at the end of which time she fell a victim to the disease of the uterus. (*New London Medical and Physical Journal*, vol. 45 and 46.) I should be inclined to offer any remarks concerning the propriety of this practice, against which various considerations present themselves, particularly in cases where, besides a severe difficulty of evacuating the bowels, another dis-

size exists, which is itself likely to destroy the patient, and in a certain not capacious of receiving any additional blood from the blood operator, procured in the example related by Mr. Hume.

Cullen conceives that the discharging vessel may be, most conveniently, probed by making an incision in the left iliacus rectus, along the edge of the quadratus lumborum muscle; and he defines the mode of operating so that of making the incision above the great right iliac blood vessel, 1, 2, p. 686; the, also, book. The discharging, however, are not obvious. (See Noddy's *Medical Observations*, f. 3, p. 320. Poppendorf, *de Anæsthesia imperiosa*, Lipsæ 1785. Remarquar sur l'Effluve des Vaisseaux de l'Anus, par M. Pott, in *Mém. de l'Acad. Royal de Chir.* 1, 3, p. 225. *ibid.* in *Ann. II. J. ABSCESSES OF THE ANUS.—FISTULA IN ANO.

The nature of giving the application of fistula to every collection of matter formed near the anus, has, by conveying a false notion of facts, been productive of such methods of treating them, as are diametrically opposite to those which ought to be pursued.

A small abscess or boil, from a large or deep cavity, discharging a thin glut or stasis, tends, as Mr. Pott has explained, a considerable part of the idea which our ancestors had of abscesses were, wherever caused. With these notions they always connected a notion of callosity; and therefore, whenever they found such a kind of opening, yielding such sort of discharge, and attended with any degree of tenderness, they called the complaint a fistula. Supposing this callosity to be a diseased alteration made in the very structure of the parts, they had no conception that it could be cured by any incision but by removal with a cutting instrument, or by destruction with escharotics; and therefore they immediately attacked it with knife or cauter, in order to scoop out of these parts; and very terrible work they often made.

That abscesses formed near the fundament do sometimes, from bad habits, from extreme rage, or from gross alimentary, become fistulous, is certain; but the majority of cases have not at first any one characteristic or mark of a true fistula; but rise, without the most exact neglect on the side of the patient, or the most ignorant management on the part of the surgeon, degenerate or be converted into one.

Collection of matter from inflammation (wherever formed), if they be not opened in time and in a proper manner, do often burst. The hole through which the matter discharges is generally small, and not often attended in the next observation or some disposition part of the abscess: it therefore, is said for the discharge of all the contents of the abscess; and instead of closing restricts itself to a smaller size, and becoming hard at its edges, continues to drain off what is furnished by the diseased sides of the cavity.

When an abscess near the anus bursts, the suppuration of the local office: the tenderness of its edges; no being fixed to let the matter from a deep cavity; the daily discharge of a thin, gloey, discoloured kind of matter; and the migration of the parts round about, have all contributed to raise and confirm the idea of a true fistula.

Abscesses about the anus possess themselves in different kinds.

Sometimes the attack is made with symptoms of high inflammation; with pain, fever, rigor, &c., and the fever subsides when the abscess is formed.

In this case a part of the lymph near the anus is considerably swollen, and has a large circumscribed fistulous. In a short time the middle of this hardness becomes hot and inflamed; and in the centre of it matter is formed.

This (on the language of our physicians) is called in general a pimple; but when it appears in this particular part, a pimple.

This pain is sometimes great, the skin tight, the tumour large and constantly tender; but however disagreeable the appearance may have been, it however keeps the symptoms may have some salutary operation, yet when this and is finally and fully superseded, the patient generally becomes easy and cured; and the matter formed under such circumstances, though it may be plentiful, it is good.

On the other hand, the internal parts, after such pain, attended with fever, rigors, &c., are sometimes attended with considerable inflammation, but without any of that circumscribed hardness which characterizes the preceding nature; instead of which the inflammation is extended largely, and the skin seems in suppuration kind of appearance. In this the disease is deeper-seated; the quantity of matter small, and the cellular membrane grows to a considerable extent.

Sometimes instead of either of the preceding appearances, there is formed in this part what the French call a suppurative granulation; in which the cellular and adipose membrane is affected in the same manner as in a carbuncle.

In this case the skin is of a dirty red or purple kind of colour; and although tender than when in natural state, yet it has, by no means, that degree of tenderness or heat, which it has either in pimple or in carbuncle.

The patient has generally, at first, a hard, full, painful pulse, with great thirst, and very frequent evacuations. If the progress of the disease be not stopped, or the patient relieved by medicine, the pulse very changes into an unequal, loose, intermitting one; and the strength and the spirits sink to such manner as imply gradual and insensibly impending death. The matter formed under the skin, as observed in small is quantity, and bad in quality; and the abscess continues to progress and enlarge throughout the extent of the inflammation. This generally happens in persons, whose habit is either naturally bad, or has been relaxed by intemperance.

Sometimes the disease makes its first appearance in the induration of the skin, near to the verge of the anus, but without pain or alteration of colour; which hardness gradually softens and suppurates. The matter, when let out, in this case, is small in quantity, good in quality; and the cure is superficial, clean, and well attended. On the contrary, it now and then happens, that although the pain is but little, and the inflammation apparently slight, yet the matter enlarges in quantity, bad in quality, extremely offensive, and proceeds from a deep cavity below.

The place also where the abscess points, and when the matter, if let alone, would have its way, is various and uncertain. Sometimes it is in the middle, at a distance from the anus; at other times, near the verge, or in the perianth; and this discharge is sometimes from one orifice only, sometimes from several. It may indeed be not only as coming through the skin externally, but matter through the fissures into the cavity: in either, there is no difficulty, and that either external or internal.

Sometimes the matter is forced at a considerable distance from the rectum, which is not even last long by it; at others, it is not last long, and not perforated. It is also sometimes not only drained, but poured; and that in many places than one.

All consideration of preventing suppuration is necessary out of the question; and our business, if asked at the beginning, must be to moderate the symptoms; to forward the suppuration; when the matter is let out, to let it out; and to break the ways to such manner as shall be most likely to produce a speedy and lasting cure.

When there are no symptoms which require particular attention, and all that we have to do is to assist the nature of the nature, a soft pouice is the best application. When the disease is that of the phlegmonous kind, the thinner the skin is suffered to become before the abscess is opened, the better; as the induration of the parts about will thereby be the more dissolved; and, consequently, there will be the less to do after such opening has been made. This kind of tumour is generally fixed in people of full, sanguine habit; and who, therefore, at the time the great, and the fever high, will bear evacuation, both by phlebotomy and a rice cathartic: which is rare when the case of those, who are said to be of bilious constitution.

first member of the family, which must have lived in St. Elizabeth's Hospital, within three or twelve years. I do not deny that, that I was not met with in the environment before described, that has not been noted by many people. However, whether with light, my drawings, and that I have seen, in all that time, which for this purpose, a small group of people, in an old house, in the city.

Let us now express the music which the theory of Poincaré himself has made its point, as it is called; and to do so by the text.

Where each point is, that is, where the skin is most dry and the hairless most palpable, the opening most readily made is by using a sharp needle with a cutting movement, not sliding, as with a safety razor.

When a discharge splits, it is not being deflected or misdirected; it makes its own way out, by tearing the critical parts somewhere near the "neckline" or by eroding and making a hole through the neckline and the armpit — or sometimes by both. In either case, air-discharge is made sometimes by one way only, and sometimes by more. Those in which the nipple has to be escaped by water-moist openings through the skin only are called *blind internal fistulas*; those in which the discharge has been made into the cavity of the ducts, without any orifice to the skin, are called *blind internal*; and those which have an opening both through the skin and into the air-moist cavities are called *double*.

Thus, all these cases are detected situations, often hardly any of them ever are so; and most of them becoming. They are still mere abstractions, which are based without the help of art; and, if taken power and kindly care of, will require no such treatment as a true friend who monthly must be used of.

The most frequent of us knowing are called the blind externally and the complete. The method whereby each of these attains the knowers is, by introduction: he probes into the sides by the surface of the skin, while the forefinger is resting on the crown; this will give the exposure an opportunity of knowing exactly the true state of the nose, with all its deformities.

Whether it is the skin that is called "eczema" (itchy skin) or not, that is, whether there be an "eczema" in the strict, medical, or otherwise, and whether in the latter case, the appearance of the skin is such as to cause "eczema" (itchy skin) of the former, the essential condition is the same: the inflamed redness of the skin disappears, the scales, which at first was sticky and that, after a day or two are passed, become more and more as if it were the discharge, by drying the parts about, restores the natural skin surface.

As this kind of sweating seldom proves sufficient for a cure (though at sometimes does), the leprography, in some degrees avoided, and if the urines happen not to be a dropping one, some part of the matter lodged, and is dissolved by intervals, or may be ejected still by the fingers of an excretor. The disease, in this state, is not very painful, and it is treacherous, easy, and effusive. The continual discharge of a thin kind of fluid from a mucous canal, and violent excoriation in the parts above, it avoids the limbs of the patient; and it, at times, very fluid; the urine also sometimes contains so much as not to be sufficient for the discharge, and the tenderness of the micturition ceases from discharge.

The means of data proposed and justified by our discussion were those, for example, ligature, and non-

The innovation in each of these is the same, viz. to form an array of the water and asbestos by laying the fibers into the water. The QWC 190 are now completely, and most accurately, classified.

Whitely no longer considered the disease either as an ailment from which the patient has been let out by an indulgent, facile or a cunning; or from which the consolation has been dispensed by one still so weak, formed by the bartering of the vital sentiments about life's enjoyment. Let us have later notice of a patient, instead of this still speaking, there are several.

This state of the case generally happens when the quantity of material collected has been large, the information of considerable extent, the papers numerous, very complex, and the time very short before it must be turned in. It is, indeed, a circumstance of so real consequence at all; but being so misunderstood, to see properly attended to, is made one of the most terrible

to the patient, and additional stains to the tissues viewed
practitioner; for it is largely, and frequently believed,
that each of these lesions is an evil in itself, or leads to,
a distinct virus, or disease; whereas, in truth, the cause
is most commonly quite effluvia; all these eruptions
are only secondary signs, heralds of the war now
being waged; and, so to say, they for or deny, lead
and open immediately into the one single event of the
disease: they neither indicate, cure and so we are
caused by, distress or assist; nor would the appearance
of twenty of them (if possible) necessarily injure them
than one, or even before.

In the second, for a true one, it will follow, that the treatment of this kind of case ought to be very little, if at all, different from that of the preceding; and that of that may be necessary to be done, may be to divide each of these grilles in such manner as to make one cavity of the whole. Thus the proboscis will easily and expeditiously do; and afterwards, if the pore, or more properly osicles, should make a very small, narrow aperture, the removal of a great number of such ungraceful angular parts will answer all the purposes of making room for the application of dressings, and the procuring a smooth even surface after the sore shall be healed.

When a considerable quantity of matter has been removed by the scalpel, and the external parts are set well in a circle, discoloured matter, but having not yet had time to collapse and approach each other, the inside of each cavity will appear large; and if a probe is pushed with any degree of force, it will pass in more than one direction into the cellular substance by the side of the incision. But let us let the expectorated practitioner be allowed all time, and immediately fancy that there are so many distant lesions, neither let him, if he be of a more liberal disposition, go to Wood's *Anatomical* with his director, blade, or scissors; let him enlarge the external wound by making his incision freely; let him let all the separate cavities open into that cavity; let him divide the tarsus lengthwise by means of his finger in two, let him done lightly and easily; let him pay proper attention to the sides of the patient, and pull and see what a few days, under such conduct, will produce. By this he will frequently find, that the large cavity of the abscess will become small and clear; that the inflammation round about will gradually lessen; that the probe will suppose to find no more into the cellular substance; and, consequently, that the force of a multiplicity of discharges were gradually. On the contrary, if the sore be treated as directed with irritating or escharotic medicines, all the appearances will be different; the hardness will increase, the lips of the wound will be inverted, the cavity of the sore will become large, crude, and foul; the discharge will be thin, slow, and discoloured; the patient will be uneasy and febrile; and, if he were crutches are turned by the irritation of pain and confusion of manner, yet the original use will have the opportunity of oversteering itself, and may very possibly become truly fatal.

Sometimes the matter of an abscess, formed just as even, instead of sucking its way out through the skin externally near the wings of the arm, or in the back, perforates through the internal only. This is what is called a *bone* internal abscess.

In this case, after the drainage has been made, the greater part of the inflammation subsides, and the patient becomes easier. If this does not produce a cure, which sometimes though very seldom happens, some small degree of inflammation generally remains in the lungs where the original linear scar; upon pressure on this lamina, a small discharge of matter is frequently made per aram; and sometimes the rupture of air from the cavity of the abscess and that of the arteries may very painfully be felt and easily heard; the vessels, particularly if large, and retaining force to be expected, are sometimes secured with matter; and although the patient, by the healing of the abscess, is relieved from the severe pain which the existence occasioned, yet he is seldom perfectly free from a dull kind of oppression, especially if he has not any considerable length of time in one posture. The great difference between this kind of case and that in which there is an external opening (with regard to method of cure) is very essential; for an external opening must be made, and then all difference ceases. In this, as in the former, no cure can reasonably be expected until the cavity of the abscess and that of the system are made

Mr. Travers has related, this is sometimes the best mode of relief.

"In the ordinary situation of peritonitis (within peritonitis has formerly designated, the position of incision sustained by the structure *cecalis* in position shortly passed. Their contiguous edges partially adhere, or the remainder of their circumference they adhere to the peritoneum, living or dying of the structure. The existing adhesion of the contiguous lines strengthened by the adhesion of the parts in contact, form a partial continuity upon the sensibility of the subperitoneal part. The line of incision is the lowest structure. It commences on that side of the gut which is in direct contact with the structure. As the operation advances, the opposite adhesion sides may perhaps extend somewhat, and a little, escape the circle of vessels. But it is never allowed to reach, back, where the peritoneum is delicate, the circle is simply covered in by granulations from the cellular substance of the peritoneum, uniting with those of the external or cellular surface of the peritoneum." (On the Progress of Nature of Peritonitis, *Lectures of the Anatomists*, p. 200.) It may be claimed, that both operations have contributed as favorably accurate ideas of the changes which Nature makes the wounded in the first position of incision, when an artificial one is produced; and, though Bland's *incision was circular*, as far as it went, it was not until the year 1823, when Scarpa published his valuable work on the Bland, that the wisdom of nature as such operation was completely elucidated. The Bland was (page 44) some how always parallel of peritonitis with the vessels contained in a tumor, and even when it does slough, slough the situation of the dead parts happens on the outside of the abdominal ring, there almost always appears in this situation a portion of the neck of the tumor perfectly sound. It may be said, therefore, that in all cases, immediately after the destruction of the intestinal intestine, whether it happens within or on the outside of the ring, the two orifices of the gut are enveloped in the neck of the Bland, which, soon becoming adherent to them by the effect of inflammation, serves for a certain time to direct the feces towards the external wound, and to prevent their effusion in the abdomen. In proportion as the enteric wound diminishes, the internal portion of the neck of the Bland is also consumed; but, that part which embraces the edges of the intestine, gradually becomes longer, and of length forms a kind of membranous, funnel-shaped, imperforate cavity, which enables the communication between the two parts of the bowel. However, according to Scarpa's explanation, this adhesion of the neck of the Bland and, round the two orifices of the gut, does not hinder the feces from gradually passing the ring, and becoming more and more deeply placed in the cavity of the abdomen. The idea of the above-described funnel-shaped membranous cavity, corresponds to the Bland, and its apex tends towards the wound or orifice.

But in relation to this part of the subject, there are some other circumstances, which every surgeon should well understand, and his ignorance of them would be extremely on the ground of their not having been, like the funnel-shaped membranous cavity, leaving the communication between the two orifices of the bowel, only a diameter of recent date; for they were fully exposed many years ago. I have already to the exact position of the two portions of the bowel, with respect to each other, the direction of their vessels, the angle or ridge between them, and the difference in their diameters. The first of these circumstances, viz. the position of the two parts of the bowel, was correctly described by Marshall, and, as we have seen, pointed out by Mr. Travers, who requires them to be occupied a position easily parallel, and calls an interesting observation recorded by Pigeot. The patient was a woman, 45 years old; the loop of sigmoid gut was three feet six inches long; the substance of the bowel when cut through the wound for a considerable time, and an artificial anus was established. Some accidental obstruction occurred; a purgative was given, which operated in the natural way; and, in fifteen days, the wound was healed. She lived in perfect health to the age of 61, when she died of a disease not connected with this injury. Pigeot presented the body, and has given a figure representing the union.

The liver, the stomach formed an acute angle, when in adhesion, to the peritoneum, opposite to the central arch. The right side is evidently much contracted. Pigeot particularly directs upon the angular position, and comparison of the tube at the point of union. The lower contraction of the intestinal tube was also limited, to be more contracted than the upper portion; a circumstance correctly referred to by Mr. Travers, in the isolated state of the bowels, situated between the artificial and the natural anus. (See *Ann. de Chir. et de Chir. 1844*, p. 104; and *Travers on the Progress of the Intestine*, p. 204.) The two ends of the bowel, as Scarpa has observed, are always found lying in a more or less parallel manner by the side of each other; the upper, with its convex aspect, and directed towards the external wound by the feces, which issue from it; while the lower, which gives passage to passing, becomes less convex, and is introduced farther into the abdomen. Hence, the bowel in the abdominal cavity is never supported by the action of the upper and lower portions of the bowels meeting, embracing, and resting, as it were, side each other. Instead, they pass at a very acute angle; the side of one does not correspond to that of the other; and their sides lie in nearly opposite each other. It is at short by means of the funnel-shaped cavity, formed by the means of the Bland, that the two parts of the bowel communicate, and the feces, in order to get from the upper into the lower contraction of the intestine, must first pass in a serpentine track through funnel-shaped cavity; there being between the edges of the bowel, directly opposite to the communication between the ends of the intestine and that of the funnel-shaped membrane, a considerable projection, projecting such, forming a natural abdominal obstacle to the direct passage of the feces from the upper into the lower portion of the intestinal tube. (See Scarpa's *Ann. de Chir. 1844*, p. 104; and *Travers on the Progress of the Intestine*, p. 204.)

Bland, after pointing out the efficiency of the adhesion, between the upper part of the bowel and the edge of the opening in the peritoneum in the abdomen, in preventing extravasation, remarks, that though adhesions are valid, the abdominal peritoneum would form a natural for the portion of the canal which has been destroyed, and the contents of the bowel would continue to pass on itself towards the anus, if the junction in the intestine, separated and adherent to the peritoneal parts, did not form such an acute angle as obstructs the passage of the intestinal matter. The more acute this angle is, the greater is the obstruction; when the two parts of the bowel lie nearly parallel, the entrance into the lower portion of the canal is completely prevented, but, if they meet at a right angle, then more or less of the contents of the upper portion may be introduced into the lower. The first disposition chiefly happens, when a considerable part of the intestinal canal has been destroyed, or when the tube has been completely divided; while the second position is principally remarked in all cases where the injury has been less extensive. And it is plain, that the possibility of a cure depends materially on the kind of angle at which the two portions of bowel meet, and the the position of the intestinal function, or failing mechanism edge between the two orifices, is always a greater or less obstacle to the cure.

With respect to the direction which occurs in the diameter of the part of the intestine united between the artificial opening and the natural anus, Bland notices the contraction of the obstruction, but entirely directs from within without or from within at the entrance, as sometimes proceeding so far, that an intermediate distant portion of the intestinal tube is the consequence. The factors involved within it, surface is presented (this contraction is a contraction which, in this case, is capillary, and is partly caused by the contact in the form of white lines. And if any further proof were needed, that the bowels between the artificial and natural anus resemble peritonitis, it will be added by the fact, that in cases of artificial anus, the lower contraction of the tube frequently becomes inverted, and protrudes. On the other hand, the kind of contraction above spoken of, has never been demonstrated by dissection; it was interrupted by Lenoir, in the contraction of the body of a person, who died twenty years after the entire extirpation of the majority of the peritoneum, but just it found to exist by the

small, when he ejected a patient who died of marasmus in the Hotel-Dieu, at consequence of an artificial anus, which communicated with the rectum, and had lasted two years. — (*Gazette de Médecine*, t. 4, p. 231 — 235.)

Hæmorrhoids proper are sometimes an artificial anus may be in many cases, in which the patient's life depends upon the event, it would be continued that the consequence is a most distressing and disgusting disorder. This kind of anus is formed, though the feces which are discharged, from not having time to be converted in the intestine, into a solid mass by compression and evaporation in the rectum. As the event, which gives rise to hæmorrhoids is not the direct result of some degeneration at the lower end of the intestine, and as, in particular, it is not connected with any extensive disease of structure, and retains itself as a disease requires, this form is essentially curable without any knowledge of the conformation of the part of the patient. Hence the salutary state of the anus during the critical opening; and they frequently external, hæmorrhoids. — Some persons in this state, usually the subject of those whose hæmorrhoids are cured, make use of a rectal fist, in which their excrement was retained. — Sometimes, indeed, the case of an officer, who was wounded in the rectum, and who allowed his feces to escape into a vessel made for the purpose. — (Hæmorrhoids a similar case.)

Mucous also communicated to the Analogy of Surgery the history of a wounded man, in whom an artificial anus took place, in consequence of a wound in the sigmoid flexure of the right hypochondrium. His recovery was used to be effected, as a few days, followed by that with a fist. The wound received a better opening, in which the rectum was accommodated.

Uncertainty is not the only inconvenience of an artificial anus. Persons have been known to be quite distressed by the effluvia, and even ultimately to die in consequence of it. This is liable to happen, even after the artificial canal is opened very high up, so that the patient escapes before fermentation is completed, and the nutritious part of the food has been taken up by the hæmorrhoids. In this circumstance, the patient becomes emaciated, and sometimes perishes, as Broussais had an opportunity of observing; and examples of which are also recorded by Boerhaave and Le Boer. In cases of this description, the matter would have little time, and is frequently vomited. In all instances, the matter is evacuated immediately, because there is nothing like a sphincter. But when the opening only connects the lower extremities of the intestine, or, what is more frequent, when it has occurred in the large intestine, the danger is less serious, and persons in this state are often noticed performing all their functions very well; and, with the exception of pain, to which they are subject, enjoying as good health as they are previously to their having the present disease. In such examples, the matter would be more fluid, its discharge does not follow so quickly, its introduction into the rectum, and it is retained here longer time.

Many patients afflicted with an artificial anus void to them at all from the rectum; but occasionally, a thick whitish substance, which is the natural secretion of the portion of the large intestine adjacent to the anus. Under certain circumstances, the quantity of this mucus discharged is more copious. — (*ibid.*, vol. ii, p. 226.)

The most pleasurable occurrence to which persons with an artificial anus are exposed, is a prolapsus of the bowel, similar to what sometimes happens through the anus, with regard to the rectum. The descent of the bowel is sometimes simple, only affecting a portion of the intestinal wall just above the lower opening. On other occasions the complaint is double, the bowel first descends and below the opening being protruded. This descent of the intestine being averted, the distension of the rectum very considerably in different positions. When the protrusion is caused by the upper part of the intestine, the rectum is voided at the extremity of the finger, and when the swelling occurs at the lower portion of the bowel, the hæmorrhoids are evulsed at the base of the protruded part. If observing this, it is found that the hæmorrhoids are double, it is easy to know in which part of the intestinal canal such protruded portion belongs. This consequence of an artificial anus is very common, because it greatly increases the hæmorrhoids when the patient suffers. Sometimes the hæmorrhoids are frequently caused; and

occasionally, when the evulsion of the intestine is considerable, a strangulation is produced, which puts the patient's life in danger.

I apprehend no well-attended surgeon, of the present day can doubt that formerly the frequency of artificial anus after surgery was seriously increased by the effluvia sometimes emitted by the system for the purpose of preventing them; and as Mr. Trevisan has rightly observed, the mucus reported by the patients, if they present any thing, prove this. "That the rectum had been very generally treated, when the artificial anus was introduced upon an emergency, and that when an obstructions had been at work to prevent a sufficient amount of active interference with the arrangements of nature, the case has terminated in artificial anus, so that the event either may have been a result of exposure to the surgeon. The fear of doing any harm, or the desire, applied only to the permanent features of distending the structure, dysphagia, dysphagia, and so forth, the intestine; the general adoption of which practice lately accounts for many cases for the creation of artificial anus, which are the sequelæ of hæmorrhoids." — (*Op.*, vol. 2, p. 207.)

The treatment of an artificial anus in other patients is different. The first consists in allowing the hæmorrhoids to protrude, and in preventing the discharge of the hæmorrhoids, and in preventing such bad symptoms as may arise from the disorder.

The first indication is fulfilled by the employment of silver or tin anastomosis, which are either kept applied to the external opening by means of a spring, or form themselves into a ring at the end of the artificial anus, from which the intestinal matter is transmitted through a tube, kept constantly in the opening. In general, says Desault, an elastic tube is simple, light, and capable of taking any shape, it is the best material for the construction of such instruments, which, however, rarely answer their purpose completely, and always give the patient a great deal of trouble.

As for the second indication, Richter, with the view of hastening the complete escape of the intestinal matter, and the death of the patient from this cause, proposed covering the opening for a certain time with a piece of sponge, supported by an elastic bandage or truss. But Loeffer found this method objectionable, as it was apt to bring on colic, constipation, and an inflamed excoriated state of the skin.

When the anus opening is disposed to contract too much, and hæmorrhoids arise from this change, Richter is an advocate for preventing such change by means of a stick or silver of silk, introduced into the aperture, and changed very often for the sake of cleanliness; and afterwards under a ring of linen for the purpose. But the irritation produced by the matter involved by this sort of effort, and in particular the facility of the bowel to protrude, and be strangulated in the opening of the every ring, are found among objections to these practices; and according to Desault, the sponge employed by Richter also becomes a great deal of excoriation by the irritation of the feces which is lodged in it.

For the purposes of hastening a protrusion of the gut, or keeping the opening sufficiently previous, of relieving any tenderness and constriction, or keeping the intestinal matter from stopping in the intervals of vomiting, and causing a loath enough for the adequate maintenance of the patient, Desault proposed a linen test or support covered by equal elastic, compresses, and a tight bandage. At first, says he, the patient feels some tenderness from this plan, and slight colic may be the consequence of it. But, by degrees, the parts become habituated to their new state, and every thing goes on well. With respect to the employment of water and plugs with the hæmorrhoids, when introduced, I am disposed to think the practice not quite so objectionable; and that any tendency for it may be relieved by attention to diet, and the occasional exhibition of some laxatives and cathartics, as well as to moderate motion. When the gut protrudes, the rectum is to be exposed in the same way as in a strangulated hernia; but some difficulty will occur when the protruded part is inflamed, thickened, and of considerable size. Indeed, surgeons have usually regarded the protrusion as unprofitable in these circumstances; but recently, but in Desault's this is not the case, as compared with a bandage, kept up for some days, will succeed. Care must be taken, however, to keep a sufficient opening

introduced one of the blades of the speculum into each portion of the gut, and closed the instrument with the screw. The part of the instrument inserted externally to the ridge of the anus, being covered with ointment and a compress. The compression was soon followed by colic pains and tenderness in rectum, complaints which were quickly relieved by stimulating the belly. They recurred, however, the instrument became loose, and some discharge ensued. On examination, the speculum was found to be partially directed. After the breadth of the instrument had been increased it was applied again; but when the screw was turned, the patient began to suffer such violent pain over the whole of the abdomen, that it was necessary to discontinue the pressure; and as the instrument was afterward removed from the rectum in a fit of vomiting, it was withdrawn. A trial was now made to determine the force towards the rectum by pressure on the external opening; but this could not be resisted, and the hindrance to the action of the intestinal matter which compresses it was discontinued. As the faeces voided by the sigmoidæ were still not taken sufficient hold of the speculum, six days it properly, the instrument was successful always. A particular description of its improved make has been inserted by Bruns in *W. Arch. Journal*, &c. 4, p. 304. Dr. Bruns has published three cases in which it was successfully employed by Dupuytren. In the first of these cases, when the instrument had been applied, a complaint he supposed to exist, that it could not be displaced from it. The pain attacks, vomiting, diarrhoea, turned sanguine, and loss of appetite, which ensued, went away after the belly had been disordered; the constriction was then relaxed, and failed to produce loss and less inconvenience. On the 24th, very little of the faeces came out of the artificial anus, and after a short time, five natural evacuations took place. The blades of the instrument were now regularly closed, and on taking it out, a streak of sanguine was found between the blades; a proof that the speculum was directed. On the 26th, the patient's health was established. The cure was now unaccompanied with the pain of promoting contractions in the natural rectum; and the next day, the patient had a proper motion without any assistance, and a very satisfactory use of the force passed out of the artificial opening. This apparatus was now, severely covered with ointment; but as some high granulations were rising, the portion of ointment was sprinkled on these, and compresses and a bandage were applied. The use of clays was also daily continued, though the patient needed his food in the natural way. On discontinuing the external pressure, the quantity of discharge from the artificial opening diminished; and, therefore, on the first of October, the compresses were again applied, and kept on the part with a slight tension. The treatment ended in a perfect cure.

In another case, Dupuytren entered the lower sigmoidæ the water speaking with a history, and water forcing with his finger that both sides of the sigmoid were close to that opening, he applied the speculum. In the evening, the constriction was loosened, which was followed by seven more pains over the whole abdomen. They subsided, however, the following day. From the water speaking, a great deal of bloody mucus was discharged. The constriction was not increased. On the 24th day, the patient was attended in the night with pain and vomiting. The following night he was also very restless. Though the belly was not tense, it could not bear to be touched. On the 15th, and the 16th, the patient was nearly free from pain, and by means of clays, two natural motions were procured; and on the 17th, as the patient was dying, Dupuytren began to make pressure on the sigmoidæ opening. On the 18th, the blades of the speculum were touched with linear cauterization, and on the 20th, a compress supported by a spring frame was applied. The patient was kept constantly in the horizontal position; the food began to be voided the natural way regularly, and the evening commenced in the most favorable manner.

I think the generality of surgeons will agree with Dr. Rouget, that the foregoing treatment cannot be indiscriminately adapted to all descriptions of patients without danger. It should never be used long after the formation of an artificial anus, but must be delayed till the irritability and sensibility of the gut,

and especially of the sigmoidæ, to be destroyed by the effect of hot air and the pressure of the force. Nor should the trial ever be made, as it has been lately ascertained that sailors cannot resist being asked the cure. Brunsch's treatment has example in within the foregoing method could not have been practiced, in consequence of the morbidness of the lower portion of the bowel having been obliterated by the pressure of a large iron three inch diameter, which had been worn by the patient two years, and the projecting edge could not be removed. (See *Bruns's Journal*, &c. 4, p. 304.) Many other interesting observations on this new proposal may be gathered in the memoir by Dr. Brunsch, and in Dr. Rouget's treatise, the title of which is given in the list of works at the end of the present notice. In order not to enter the risk of an overstatement of the benefits the abdomen, the construction of the speculum should never be compared with that which have before the influence, inflammation has and time to be produced between the layers of which that part is composed.

In cases of artificial anus, the appearance of the sigmoidæ end of the bowel undergoes some change, in consequence of exposure to the air and the contact of extraneous bodies; it becomes thicker and less villous, but does not cease to exercise a peristaltic action of spasm; this is one of the principal reasons why it is so difficult to close the fistulous opening, even when the passages for the feces have been restored. This also serves as an indication as to the necessity of very gentle, and modified externally directed by the contact of the instrument. (See *Bruns's Journal*, &c. 4, p. 304.)

If after the destruction of the sigmoidæ, the peristaltic action of the sigmoidæ is lost, the external force was not to assist it being hindered by phlegm and other necessary means, no doubt could be entertained of the propriety of resorting to the plan of attempting to raise it by means of sutures and ligatures then applied with external, as is sometimes done by Dupuytren, or the Tassoul's procedure, as successfully described by Mr. C. P. Colles. (See *Med. and Physical Journal*, for June, 1834.) Dupuytren, for the purpose of making the sides of the fistula remain in contact, or raising them towards each other, occasionally applied an apparatus with the instrument consisting of two rods, which by means of a screw can be made to embrace the fistula. An engraving of it may be seen in *Bruns's Journal*, &c. 4, p. 304. For the closure of the fistula, Dupuytren also sometimes has recourse to the silver cylinder.

I shall conclude with the relation of an interesting case of artificial anus complicated with proptosis, as recorded by the friend Mr. Lawrence.

"I the complaint is, mentioned (in the) terminates in the formation of an artificial anus, we must endeavor to alleviate these distressing inconveniences which arise from the involuntary discharge of wind and feces through the new opening, by suppling the posture with an apparatus in which these may be retained as they pass off. An instrument of this kind, the construction of which appears very perfect, is described by Richter (*Lehrbuch der Wundheilkunde*, vol. 5, from the *Threat of a Synopsis of Jussieu*). The patient will be best enabled to resist any contrivance of this sort in the general circumstances of his own case. It has been found in some instances, that a compress elastic frame with a compress of lint under the pad, has been more serviceable than any complicated instrument (*Periodic Journal*, vol. 1, p. 181) in preventing the external part of the rectum from the artificial opening." (*Cyclopædia of Medical Art*, p. 220.)

"I know," says Mr. Lawrence, "a patient with an artificial anus, in whom the proctitis protrudes in the length of eight or ten inches, at the same time swelling from its surface. This is attended with pain, and discharges him to the down, to which position the intestine recedes. The patient has been discharged all the feces at the great sigmoidæ, and has enjoyed considerable health and strength during the time. His evacuations are generally first, but sometimes of the yellow coloration. Whenever he retains the stool after feeling an accumulation to void it, a quantity of clear mucous mucus like the white of an egg, amounting to about four ounces, is expelled from the anus; and this may occur twice or three times in the day."—(*ibid.*, p. 221.)

We hasten as much as possible the immediate preparatory measures, in order not to prolong unnecessarily the residence and cause agitation which the expectation of an operation, and maintenance of the slightest uneasiness, produces. These precautions are neglected by the English surgeons, at least by most of those whom I saw operate. They even carried them to the extreme, where, more commonly than in hospitals, we have to deal with post-humous individuals, who are easily alarmed, and whose extreme susceptibility it is of importance to soothe. It was in the very room, where the patient lay, of course under his eyes, that the table and all the necessary instruments for lithotomy were arranged, at an insertion which I saw done in London, during my stay at that capital, by a gentleman at the head of the profession.—(See *Paralysie de la vessie* de *Cherbourg* par le *Chirurgien* *Francçois*, p. 253.)

M. Roux, in his visit to London, had also the good reason to complain of the slovenly, objectionable practice of leaving the application of the lithotome, and the dressing of the wound, after a surgical operation, to mere nurses and students. I entirely coincide with him, that, as regards to the lithotomy, in particular, a surgeon is bound to extend his attention and vigilance to the bedside and the dressing of the patient, from the first to the last.

APPARATUS MINOR: APPARATUS MAJOR: APPARATUS ALIUS. Three ways of curing the stone.—(See *Lithotomy*.)

AQUA PITHI LAGUINIE. Blak. Taken of two pounds, water a gallon. Mix them with a vessel good for a quarter of an hour, and after the sea has subsided, let the liquid be strained, and kept in well-corked bottles. This liquor is often used in puerperal and other strumous with excellent success.—(See *Liquor*.)

ARRHENTI NITRAS. (Nitrate of silver, lunar caustic.) One of the best caustics. Its office in ulcerating indurated ulcers, and hospital strumous, from being the such, is well known to every surgeon.

Mr. Barker attributes the loss of the arrhenti caustic, on the first application in a chancre, before absorption can be supposed to have taken place. He directs the caustic to be scraped to a point, like a black lead pencil; so that when it is applied every part of the surface of the chancre may be touched with it; and he advises the repetition of the process till the last crust which is thrown off leaves the sore perfectly healthy.

This treatment, when the sore is very small, may sometimes be advantage at a distance of observing the change of the constitution being induced by absorption. In general, however, contents with the plan of the immediate use of mercury.

The important use of the arrhenti caustic, in the case of venereal disease, we shall have occasion to remark in various articles of this work; particularly *Chancra*, *ulcers of the prepuce of the Glans*; *Gonorrhoea*, *strumous of the*.

The arrhenti caustic is often used in the form of solution, in the proportion of a drachm of the caustic to six ounces of distilled water. In general, the application ought to be at first more or less diluted with distilled water. Cantharides glysters and water about the same and neighbouring parts of the face, being exempted of liquor, or cold air, or exposure, are often successfully treated by the arrhenti caustic, both in the solid and fluid state. The arrhenti caustic also may be used with certain cases which occur round the roots of the nails in the fingers and toes. The action is sometimes aided with a corn-char pencil; but is generally dropped with such tea of yolk of egg, till drying them on the part, and covering them with a plaster.

ARRHENTI is the chief ingredient in a secret remedy which has long possessed very great celebrity in London for the cure of cancer, and is now well known among surgeons by the name of Barker's caustic. This application consists of the lithotome, acris, the powder of cantharides, the following vulgar, and the less celebrated, in the proportion of an ounce of each, triturated and mixed with a drachm of the white oxide of arsenic and five scruples of sugar. The white is to be brought into a paste, formed into balls, and dried in the sun. When required fresh, these balls are beaten up with yolk of egg and spread upon a piece of pig's bladder. The use of the preparation is in destroy the

cancer, upon which the arsenic would have no effect, for it is so absorbed, that Venetian's caustic was employed for the dispersion of tumours as well as for the relief of ulcerated cancers. The application is to be made on the part twenty-four hours, at the end of which time the arsenic is to be dressed with any anti-inflammatory ointment. When arsenic was first recommended as an application for cancers, it used to be thought to be applied with opium. When Fischer's caustic is employed so as to form a scab over a sore, these are used, respectively, that just over the good, it is not by any specific effect of this medicinal preparation, but simply as a though in order to draw out the disease in any other manner. It is highly probable, also, that the ointments which have been thus prepared, have never been accompanied with the structure the materials of true scabs. With respect to cancers, most of the caustic sometimes extremely produces a degree of suppuration, which, however, rarely lasts for any considerable time; but there are many intractable ulcerations and abscesses which derive permanent benefit from the application, and are even completely cured by it. Some examples of cancer, abscesses about the roots of the nails, and repeated cancerous ulcers of the legs are of this description.

At Paris an arsenical paste is often used by Deland and other surgeons of that capital for cancerous ulcers of the penis and other malignant ulcers. It is composed of seventy grains of arsenic, twenty-two of sugar of lead, and eight of the white oxide of arsenic formed over paste with water at the time when it is to be employed. The paste and ingredients that composed the use of it (says Mr. Cruveilhier) cannot be equalled by the arsenical preparation with the best. (See *Journal of the Medical Society of Paris*, p. 45, 50, 1832.) From death may be accounted by the absorption of the poison, as appears from the two cases of cancer, the first of which is recorded by M. Roux in his *Mémoires de Médecine*. The day after the paste was applied, the patient complained of pain and severe vomiting, and in two days perished in convulsions, at the post mortem examination. The body was quickly into putrefaction. The internal coat of the stomach and a great part of the intestinal canal were inflamed and worked here and there with dark spots. Just before I visited Paris (adds Mr. Cruveilhier), I descended to London a woman who died under similar circumstances, and where the same morbid appearances were presented, &c.—(Op. cit.)

Jacquemont's applications to cancer were generally combinations of arsenic and sulphur. This formula was in some of yellow arsenic with half that quantity of Arsenical salt, and sometimes to which and precipitate. He also employed a compound of arsenic and a combination of this sulphur with crude mercury. The arsenical preparation which he used, was scraped and laid on the inside of the sore, the edges of which were touched with a combination of the mixture of iron and mixture of arsenic. In some instances we have seen the effects of the treatment were the correction of the fatal result, reduction of the appearance of the sore, and separation of the cancerous part.

In the *Pharmopoeia Chimica*, Jacquemont's arsenical caustic is directed to be made in the following manner. *℞. Arsenicum pulverisat. 5j. Arseni pulverisat. 7ij.* These are to be mixed together in a crucible. The application may be reduced to any degree of thickness by mixing with this pulverized substance a quantity of oil in the form of powder, which was also supposed to be superfluous in dissolving paste.

The powder of white oxide of arsenic, mixed with other substances, has sometimes been applied upon cancers and other venereal ulcers, but the practice is now abandoned by every judicious surgeon, on account of the violent pain resulting from it, and the not unfrequently fatal consequences of its absorption. Could I suppose, that a pain so rude and transient as to remove this miserable practice yet existed in the profession, I should not disposed to mention these remarks; but I am persuaded, that it is due society, at least, more judgment and knowledge every where prevail. The white oxide of arsenic, however, may be applied with more propriety in some cases, either in one of those already specified, or as a decoction, composed of eight grains of the oxide and the same quan-

loss of matter, enlargement of the pores, fatal petechia, &c. Above, or fact, may be considered space that cause of poison which induces entirely the same effects externally applied as well as when taken internally. The reason of this, in so far as those of other philosophers, demonstrates that for instance as the space is as less than and therefore when first to receive is as an external application to demand surface than what applied directly to the element. Another possibility of the other source also further to be said: according to Professor Weyler (Lectures on Physique Medical, in some cases, even while the machine is unresponsive from the operation of the power, for again fully applied are indicated, of a motion the general healthy pulse, and death occurs equally and unexpectedly; as sometimes or much occurring in the consequences of the surgical physicians. - Weyler.)

ARTERIOGRAPHY (Pron. *ar-teer-ee-oh-graf-ee*, as artery, and vial, to end.) The operation of opening an artery. For the purpose of taking away blood for the relief of disease. (See Medicine.)

ARTICLES. The practice by which a divided or principal artery is sealed is particularly considered under the word *ligatures*; while the general principles, which ought to be observed in the application of ligatures on the sleeping of blood, may be collected partly from the remarks contained in that part of the work, and partly from what is stated in the article *Ligation*, *Arteries*, and *Ligatures*. As the treatment of a bleeding patient depends of necessity, and the preservation of life in such a case depends upon proper measures being immediately taken, it must be left to the skill of the surgeon who is not competent to the treatment of wounded arteries, whether exposed by accident or to a surgical operation. An English book observes, as general practitioners, when called in case of several hemorrhages, is thrown into such embarrassment, as actually depends less on the power of rendering blood inanimate. Pale as a corpse, and trembling, he trembles the pit of blood; and, for the sake of appearing to do something, perhaps he applies spirit of wine or a very tight bandage, and cries out for further aid; while simple presence of the hand serves a useful part in the vicinity of the injury would point out the true condition, and a dangerous loss of blood. No part of surgery, in fact, is of higher importance than the treatment of wounded arteries; and it deserves, therefore, to be carefully studied by every practitioner, whether he move in the higher or the lower sphere of the profession. And as a proof of the necessity of correct judgment making themselves unacquainted with the subject, he notices the case of a barrister, who for the instrument with which he wounded against the lower part of his leg, whereby the posterior iliac artery was wounded. The blood gushed profusely, and the surgeon, who was sent for, applied a tourniquet at the posterior artery, and thus stopped the bleeding for a time; but, unfortunately, the tourniquet was kept so long on the limb, that the foot swelled and sloughed away. — *Edin. Med. and Surg. J.* 1822, 2d. vol. 1863. From the explanation, however, in the article *Hemorrhage*, it will be seen, and it is to be regretted from considerable arteries, undeviatingly to the ligature, as a means of preventing the further loss of blood; and it may be tied down as a final remedy, that such extremity of the wound would almost be tied as nearly as possible to the wound in its course. As Mr. Thompson has remarked, "the necessity of tying both ends of a wounded artery is evident from the fact, that the anastomosis in all parts of the body are so extensive, as to furnish a supply of blood which may pass through the lower extremity of a wounded vessel in a sufficient stream to produce a bleeding, not, in some instances, a fatal hemorrhage." — *The Doctor of Arteries*, &c. p. 461. This great observation is followed by a case, in which the artery from the lower end of a divided femoral artery passed the patient's death. Of course the inference is, that both extremities of the vessel ought to be tied down directly after the receipt of the wound. As regard to tying the trunk of an artery at a point the less where it passes increased with facility, we find the following notice its bleeding extremity, Mr. Thompson observes, the practice "was directly traced from a knowledge of the fact, that the ligature was given at a distance from the disease, and effected more of its cure." — *Edin. Med. and Surg. J.* 1822, 2d. vol. 1863.

"conforms with the condition of a flesh after such an operation, and the processes by which the cure of an aneurism is effected after the modern operation, afford a curious illustration of the efficacy and danger of this mode of treating a wounded artery; for it is now fully proved, that when an artery is torn, a structural blood-clot forms to plug the opening & to slow the ligature." (P. 421.) This total disregard of science is absurd, however, that a student doctor, in which all the upper end of a wounded artery is torn, and yet the patient recovers without hemorrhage from the lower orifice, which is closed by the natural processes.

In the Year 1844, in Richmond, I took up the Femoral artery, in the middle of the thigh, in a case in which the ligatured artery had given way, one day after the passage of a needle and thread through it. I saw only one single small ligature, which was applied with the permission of not detaching the artery from its natural connection. The hemorrhage was effectually stopped, and the wound healed in the most favorable manner. Here, no doubt, the infirmation in the lumen had obliterated the portion of the artery immediately below the point at which it had sloughed or abscessed, and those ligatures have been from the same cause some ligatures of lymph within the upper portion of the popliteal artery, contributing to the arrest of the operation. But, no doubt, it was the destruction of the capsule of the circulation by the ligature of the Femoral artery, which enabled nature to complete the obliteration of the wounded part of the vessel. Consequently, says Mr. Hodgson, when hemorrhages take place, a few days after the bleeding from a wounded artery has been stopped by compression, one extremity of the vessel will be pervious, while the other will have closed by the natural processes. Cases have even occurred, in which the upper end of the artery has been closed by the natural processes, while those processes failed in effecting the obliteration of the lower extremity of the vessel, from which a serious hemorrhage took place. (Hodgson, op. cit. §73; and Galtier, in New Med. and Phys. Journ. vol. 4, p. 177.) Indeed, in the example in which I took up the femoral artery, myself, it was impossible to say positively, whether the blood came from the part of the popliteal artery above, or below the point at which an incision was made into the lumen.

The principle, regarding the application of a ligature to each end of every large divided artery, is to be extended also to punctured arteries, one ligature being placed above and the other below the opening in the vessel.

From some observations in the article *Amsterdam*, p. 125, it will be seen, that when the impulse of the circulation has been lessened by the ligature of the main trunk of an artery, some distended vessels wound, the hemorrhage from the same remote portion of the vessel may sometimes be effectively restrained by pressure, which, previously to the stoppage of the great current of blood to the part had proved unavailing. This fact is worth remembering, in cases in which the arteries of the hand or foot are torn.

Hemorrhage is observed to be more frequent after the ligation of an artery for a wound, than for its anastomosis. In regard, Mr. Thompson very correctly, I think, refers the difference to the mechanical injury of the surrounding parts, and particularly of the veins and nerves, into the loose blood, and want of spasm and proper care after the accident. The principal anastomosing vessels are the same as described by ARNOLD.

Myers writes also about the "baleful" (p. 173),
"baleful" again, in the article *Arrogance*, the secondary
baleful, how to cut down by and the many of the
baleful article, I shall conclude the present subject
with a few instructions: how to cut up the articles of
the *Arrogance* and *Arrogance*, as declared by Myers, Mr. C.
and Mr. H. and *Arrogance*. Some instructions how
to cut is a case of uncuttable *Arrogance* and *Arrogance*
baleful.

In order to lay bare the radial artery at the upper end of the forearm, a finger is to be put on the insertion of the tendon of the biceps. A little below this point, as it is, about two inches and a half in length, is to be made in the integument, in the oblique direction, denoted by the lower edge of the supinator radii major. The supinator major is then to be divided, and the inner edge of the incision made nearly a little from the outer side of the arm: as the gap is between the muscle and the flexor carpi radialis.

male and the patient died of a sort of dysuria. When the trocar is short, the bladder, on extending and contracting itself, gradually quits the cannula, which becomes useless, and a necessity for the trocar without therefore may be planned. Whenever plans may be taken to direct the trocar obliquely downwards and backwards, serious consequences may be, in some degree, prevented by the axis of the bladder, and in the other of those accidents must always be prevented.

These preventives, however, may be effected by merely employing, instead of a straight trocar, a curved one, which will naturally take a certain direction. The improvement was suggested by John Jones, the inventor of the lithotomy needle, who also pointed to a curved trocar for this phenomenon in the bladder, very superior to the instrument of the same shape previously in use.

To this way of operating Mr. Sharp was partial, and Mr. Abernethy has recommended it under certain circumstances. The former remarks that it is an operation of no difficulty for the surgeon, and of little pain to the patient, as the trocar does in the bladder being at a distance from the parts affected. It is equally applicable, whether the bladder be at the neck or the prostate gland; and when there are strictures, the use of trocars may be continued, while the cannula remains in the bladder. — (*Critical Inquiry*, p. 175, col. 4.)

Some writers recommend making an incision about two inches long through the skin at a little way above the pubes, and then introducing a trocar into the bladder. Others deem this preliminary incision quite useless, alleging that the operation may be performed with equal safety and benefit to the patient by puncturing at once the skin, the loose skin, and the bladder. When the trocar has been introduced, the stricture may be withdrawn, and the cannula kept in its position by a thread passed through ring holes made, with which it should be constructed, that extend round the body. The style of the cannula should be stopped up with a little plug, so as to keep the urine from driving away involuntarily, and taken out as often as may be necessary. — (*Encyclopædia Méthodique*, part. Chirurg. art. Paracentèse de la Vessie.)

The trocar should be introduced in a direction obliquely downwards and backwards. For as the correspondence with the axis of the bladder, the instrument will be less likely to injure the opposite side of that organ.

Nearly all writers advise the puncture to be made as high as is safe, and a little above the pubes. The reasons for so doing are the following: "If the puncture be made close to the os pubis, the bladder in that part, often rising with an almost perpendicular shape, leaves a chasm between it and the abdominal tegument, as, in speak more strictly, a certain depth of membrane cellularis only, so that if the trocar penetrates but a little way, it possibly may not enter into the bladder. If it penetrates considerably, it may pass through the bladder into the ureters, and not in the operation itself, some days afterwards, when by the course of the urine and confinement the patient is more troubled. For the abdominal muscles, striking and falling, by compressing the extremity of the cannula to press against the lower part of the bladder, and in a small way to make a passage into the ureters." — (*Sharp*, in *Critical Inquiry*, p. 175.) "Though the puncture here advised seems at first as formidable as they are numerous, both the danger of wounding the peritoneum from an operation so plunging is a trifle at the above distance from the pubes." Certain it is, punctures would be necessary to be induced by such position, than by introducing the instrument immediately above the pubes. Richman decidedly condemns the plan, principally because the higher the puncture is made, the more apt the bladder will be to pass the cannula as pressure being discharged. — (*New Voyage*, chap. 5, p. 175, col. 5.) In Dugue's works by Richman, the puncture is also advised to be made immediately above the pubes. — (*Y. K.* p. 318.) Some of Mr. Sharp's opinions are concerned in taking care to pass the trocar into the bladder in the part of the ureters, and expressing one which is somewhat curious, as Harvey, John Jones, Sommer, &c. have advised. Mr. Sharp confesses the danger of using too long a cannula, by mentioning an accident which occurred in his own practice. "Though he introduced the instrument more than an inch and a half above the os pubis, yet having pushed it full two inches and a half below the surface of the skin, the extremity is not at

seven days introduced itself into the bladder." — (*Critical Inquiry*, p. 175.) The instrument, with its cutting edge, should be made in such form, according as the ureter is fat or otherwise; but the ordinary height should be above two inches and a half. The operation should be uniform, and from the surface of a cyst, about eight inches in diameter. — (*Y. K.* col. 4, p. 318, par. Richman, l. 2, p. 317.)

A catheter left in the bladder longer than six days may gather such an irritation from the urine as to be only to render the operation of it painful, but very unprofitable. Surgeons, therefore, should never leave the cannula in the bladder after a fortnight, and it is not to be kept introduced so long. Mr. Sharp advises a second one to be introduced, made with as much care as the first. — (*Critical Inquiry*, p. 175.)

Mr. Abernethy, however, has reported one instance in which a catheter was kept in for a long time without inconvenience. — (*Medical Annals for the Year 1800*, 2d. ed. p. 39.) I have seen this report, and very often examples of the same kept up, mentioned by Dr. Jones. — (*Journal*, vol. 2, p. 416.)

Mr. Abernethy makes his incision between the pyramides scapulae, passes his finger along the upper part of the sympathetic gland, so as to touch the duct of the bladder, and introduces a common trocar at the middle end in a direction obliquely downwards. On withdrawing the style, he passes a middle-sized common elastic catheter through the orifice into the bladder. The cannula is withdrawn, and the catheter left into the urine passing through the ureters. After a week, as the instrument begins to be rejected by the urine, it is taken out, and a new one introduced. — (*Medical Observations*, 1804.) It might be objected to this plan of employing a hollow needle, that as it is smaller than the wound, the urine is not kept from passing between the instrument and parts over which it is introduced, as well as through the hole itself. The response in Mr. Abernethy's case, and though as true as that instance got into the cellular membrane, it might sometimes be so, because it is so often after inflammation has taken place, that the orifices of the cellular substance are closed with coagulating lymph. After a day or two, however, the contents of the tract would be withdrawn and the hollow tube employed, which would be less likely than the other one to come disengaged of the posterior part of the bladder.

The following is one of Mr. E. Hæver's comments: "When the puncture is made directly upon the cystitis which encloses the trocar is not to be fixed, all the surrounding parts have been rendered by inflammation, so as to prevent the urine in its passage out from penetrating itself into the neighbouring parts. For where the urine edges infiltration takes place. Any advantage, therefore, which may arise from a more flexible instrument remaining in the bladder, is more than counterbalanced by its not fitting snugly the aperture through the coats of the bladder, and allowing the urine to escape into the cellular substance." — (*Transactions of a Soc. for Med. and Chir. Amsterdam*, vol. 3.)

There is much truth in the following passage. The abdomen is relaxed; the preliminary incision, which prepares for the introduction of the trocar, sometimes passes through several inches of an old cellular membrane; the incision must be made as prepared as they fight; the cannula is no longer edged with steel, it is displaced, in some degree, by the contraction of the bladder, which, often expanded, remains under the pubes. The cannula stands so obliquely, that the urine never flows with ease, but by pressure out into the ureters, and by being rejected among the cellular substance, it causes the urine to remain; the wound by its proximity to the inflamed peritoneum soon becomes, and thus, notwithstanding the frequent trial produced by the movement of the bladder, the point does on the third or fourth day. — (*Johns on a Synopsis of Surgery*, vol. 2, p. 171.)

That this operation is infinitely better than that of making the puncture in the peritoneum, is undoubted. There are even now some good surgeons, who wish to prefer it to the method of exposing the bladder from the ureters. In the *Obstetric Characteristics* of 1801, l. 2, p. 224, it has, however, the advantage; and at p. 212 of the same book, a high necessity is shown in it in the following terms: "This operation is such. The little thickness of the parts which are to be

wounded, renders a quick and intelligibly painful. The patient has learned to be a soldier. The patient is neither frightened nor injured, with the pressure in which he is yet. It is almost impossible to force the bladder except at the extremely constrained. There is no risk of poisoning the cavity of the abdomen. A urinary passage, that has the bladder in its immediate contact with the wall of the abdomen, and that when this is to be distended with urine, it stretches the peritoneum upwards and backwards, rather than downwards. It is, of course, and thus carries the point of the incision lower down and more distant from the cavity of the abdomen. The patient may easily be so made or otherwise, as to be discharged at the time required by the doctor. There are here but three or four vessels of which the cavity is to be cut. No difficulty is experienced in doing the operation, and the pressure of the instrument does not hinder the patient from sitting, standing up, or even walking about in the hospital. When the patient is left in the hospital, he is never out of the hands of the nurse, who cannot possibly get it. Lastly, the wound heals with more facility, than that made in any other method.

[illegible]

This operation (according to Sir Astley Cooper) is very easily performed; it is not liable to the objections which were formerly made to it, and it is an immense gain. In the female it is the only proper mode in cases of retention of urine from retroversion, and from an obstruction of the os uteri, by prolapsus of the ovary; for (says he) opening the bladder through the vagina is a very painful and dangerous operation, as the urine afterward bubbles up that passage, where it otherwise has the highest degree of excitation, attended with dreadful suffering, and constitutional irritation. "It is an operation which ought never to be performed." —*See Cooper, vol. 2, p. 410.*

According to my own judgment, the plan which is about to be described is the noble and best, when the circumstances of the case afford a chance: and I think, that it would be for the benefit of the afflicted if the patients above the pulpit were only performed in cases in which the enormous weight of the prostate gland and disease, in the rectum, prevents it from being safely done from the perineum.

3. Purchases from the Section

This method is more generally applicable than either of the two plans above related. It is not, like the previous two, the permanent, liable to the objection; that the wound is made in a recessed or inflexed part which is subject to necrotic gangrene. Nor is it like the previous plans, the plan, attended with a chance of the same effecting itself in the cellular membrane. It has also the advantage of exposing the bladder immediately. The puncture is made judiciously far from the neck of the bladder not to expose any inflammation existing around the neck; and the operation is easily attended with little pain, since there is no skin but remains to be wounded, namely the parts of the fibrous and muscular coat, at a point where these organs do not adhere with each other. In cases of enlarged prostate gland and of disease of the rectum, however, some other method should be chosen, though I am of opinion, that in the first of these cases, puncturing the bladder at all can seldom be absolutely necessary, as the catheter may almost always be introduced by a surgeon who understands the nature of the disease and its alterations of the course of the prostate.

Worked in the palaeontological Department for 1770, at a time of local flooding of large dams structures, where the bodies were essentially powdered from the surface. The plan was suggested by Mr. Haidar, who did the specimen by his feeling the ladder knowledge, present in the region where the finger was in the hand.

The patient was placed in the same position as that for lithotomy; a tensor was passed along the finger into the urethra, and pushed into the bladder and most proximal part of the swelling, in the direction of the apex of the bladder. A straight catheter was then introduced through the urethra, just the finger by continuing through just the tube, which was then snug, and as soon as the water flow was changed the patient was again operated. During this time the pressure of the bladder remained the same and with a flow of water continued. Then the opening made by the instrument seemed to change, and the water flowed in a well defined stream again. The tensor came away in the morning five days after which a poultice was applied with the aid of a tensor, which had been passed through the opening into the bladder and which was used all of the time in the case until cured.

[illegible]

In order to sustain the friendship and other interrelationships mandating the provision of the medicine, Fierstein emphasized that it would be better to employ a little bit of a flexible substance, and some of the students approve the plan of passing a flexible valve through the liver and into the bladder, and withdrawing the liver treatment.

In the first volume of the *Annals of the Medical Society of London* two cases are related, in which, after taking the tincture from the rectum, the cannula was immediately withdrawn without any bad effect; and a similar fact is recorded in the *Medical Communication*, vol. 1.

A sword, the, of sufficient length, is the best for performing the operation, and was recommended by Ponsard. As the incision with a lancet-punt may cut blood-vessels which would bleed freely, some authors express their preference to one made with a straighter point. (*Monro*, p. 218.) It should be introduced into the junction made by the distended glans, a little beyond the prostate gland, exactly in the centre of the form of the ureters; but not imprudently far up the ureter, lest the perforation be injured. For some useful remarks on this point, the practitioner is referred to Mr. Carus, who has very properly collected in the very long paper to which the portion of penmanship is referred, over the article described. (*Ann. of the Med. Observ.*, &c., v. 178, no. 100, 1811.)

The towel should be introduced in any direction of the side of the bladder, or merely in an imaginary line drawn from the spot to be perforated to the middle point between the navel and the external os.

[illegible]

weight, and she was immediately seated with a pain in the small of her back, and a total cessation of urine. In April, 1776, she applied to Mr. Werser, who stated that she had never been able to pass the contents of the urinary bladder, and that she was in continual pain, and had daily been much weakened by having several times lost considerable quantities of blood, occasioned by the force made use of in introducing the instrument into the bladder.

Mr. Werser, upon examining the parts with his finger, which he had great difficulty in introducing into the vagina, discovered a considerable tumour, which seemed to be of a fleshy substance, and took its rise from the lower part of the bladder near its neck. When the patient strained to make water, the bladder was distended, the tumour protruded a little way out of the vagina, and then, but upon ceasing to strain it gradually returned.

A surgeon having been given two days before the operation, and the patient excited by means of an emollient regimen, Mr. Werser directed the patient to strain so as to make the swelling project. He then inserted it from within into the bladder by passing a ligature through it, and tied it round it as far as it protruded. The latter object was found impracticable in consequence of the size of the tumour. Seeing this, Mr. Werser directed the patient to compress the right side by cutting a deep furrow about half way across the neck of the bladder, which, by pulling the swelling downwards, he was enabled to do, in fact, which was very hard.

For three days after the operation, a great deal of pain was felt in the abdomen. On the sixth day the tumour dropped off. From the first day the urine came away without difficulty, and the patient got quite well. The tumour resembled a turkey's egg in shape and size. (See Werser's Cases in Surgery, 4th ed. p. 281.)

Perhaps in this case the ligature was more pressure to rupture it away, even though its force was large; or had the knife been used, there would have been some doubt of the bladder becoming diseased with blood.

For an account of other instances of the bladder, I refer the reader to *A Practical Treatise on the most important Complaints affecting the Urinary and Digestive of Urine*, by J. Huxley, 4th ed. Lond. 1822.

A case in which large quantities of hair, mixed with calcareous matter, were first taken to have extruded from the bladder through the urethra, occurred. The disease produced severe pain in making water, and other complaints resembling those of stone. At length, Delpech, supposing that the hairs were formed in some cyst, communicating with the bladder, determined to divide the duct by operation. Previously to dissection, every preparation which could be taken from the tumour was exhausted; and by gradual compression, as large as an egg, was felt in the part where the bladder and vagina nearly touch. With the lithotomy cyst, the tumour was found in the direction towards the symphysis pubis, and being taken out to divide the vagina, the tumour was found to be the bladder, and, as the bladder is situated at the side of a patient's leg, it was felt, which was easily extracted. A large mass of hair and calcareous matter was also removed, projecting at the neck, and right point of the bladder from its opening, the edges of which were of hair, and contained that the calcareous substance appeared the purpus (cysts) for their attraction. After thus dividing the aperture of the cyst, Delpech passed his finger into it, and a large quantity of hair was pushed out of the mouth. It was also removed, and the dividing found a considerable prominence within the bladder, and that it had a cystic neck which could be cut. This was afterwards done with a piece of silver wire, covered round the part by means of the ring at the end of the catheter. Five days afterwards, what had been first supposed to be a cyst, and in the opinion of Delpech was very firm and without any cyst. It is short, the ligature had only divided the cyst of the cyst, and the bladder would now be a large opening, and though from a cyst, corresponding to the opening, but because the bladder is situated. The cyst was found as a part of the bladder, and Delpech considered that the new change of cyst would result from lifting an injection into from a height of six feet, through a pipe like the eye, so as to wash it out with care.

Open. This was created pain in the abdomen, and fever, so that it could not be continued; but, after the discharge of more hair and calcareous matter, and a substance as large as a hen's egg, which was covered by calcareous matter, a more thick, the patient got well. This substance is said to have been the product of the cyst, and the way in which it lay extended to the mouth. The case is highly interesting to the practitioner. (Delpech, *Chirurgie Clinique*, t. 2, p. 521, et seq.)

Bladder, Fibrous of. See Fibrous.

Bladder, Fibrous of the Bladder. The instances in which urinary bladder has been described from the bladder are very numerous. Many cases of this kind are referred to by *Boyle's Fibrous of the Bladder*, Anatomical, 4th ed. p. 227-242. A few years ago, an interesting case was recorded by Mr. Lawrence. (See *Med. Chir. Trans.*, v. 2, p. 262, et seq.)

*Bladder, Fibrous of. Numerous examples in which this deviation from the natural structure has occurred are referred to by medical writers. The following, however, which, as far as I know, contains the most ample information on the subject, is a dissertation (1849) dissertation, entitled "De Fibrous Fibrous of the Bladder," by Dr. Ross, late professor in Brunswick, and a paper called "An attempt towards a systematical account of the appearances associated with the malformation of the Urinary Bladder, in which the writers, instead of attempting to a proper manner, only interesting in the subject of the disease," by A. Pringle, in the *Ann. Med. and Surg.*, 1849, vol. 1. In this last dissertation, may be seen references to all the most recent cases on record, both male and female. (See also *Fibrous of the Bladder*, *Practical Medicine*, vol. 1, p. 120, 121, 122, 123, 124, 125.)*

Bladder, Fibrous of. See Fibrous of the Bladder. Many cases of rupture of the bladder from stones or from other causes, followed by fatal extravasation of urine in the abdomen. Two such instances have been recently detailed by Dr. Pouch. (See *Arch. Med. Chirurg.*, vol. 2, p. 311, et seq. 1855. Also in *Medicinal and Med. Communications*, vol. 2, p. 384, 385.)

Bladder, Fibrous of. See Fibrous of the Bladder. By this operation, a solution of the taking away of blood for the relief of haemorrhage. Bleeding is called general, when procured with a view of lessening the whole mass of circulating blood; and local, when performed in the vicinity of the disease, for the express purpose of lessening the quantity of blood in a particular part.

General Blood-letting is performed with a lancet, and is subdivided into two kinds; viz. the opening of a vein, termed phlebotomy, or venesection; and the opening of the temporal artery, or use of its branches, termed arteriotomy.

Typical Blood-letting is performed, either by means of a tapping glass and a siphon, or, instead, or by dividing the vessels, and dividing the vessels with a lancet, as is frequently done in cases of epilepsy.

In the Northern and Western States, bleeding is very generally performed by the tapping lancet, while in the North and East, the blood lancet is almost universally in use. The choice of instruments must of course in every case be left with the operator, although, as a matter of convenience, it may sometimes be proper to stick in this respect to the wishes of a sensitive patient, and hence many surgeons have both at hand, whether they voluntarily prefer one or the other. The use of the blood lancet is thought by some to require less skill than the other, and hence they whose interest and common opinion is to use it; but considering their own skill in the use of the spring lancet, they give this the preference in their own hands. From what I have seen, however, in the South, where the spring lancet is in almost every body's hands, and in the North, where it is seldom seen or used at all, I incline to be of opinion that, although from long habit I employ the spring lancet myself exclusively, when the practice of the patient does not object. In the hands of an ignorant or awkward phlebotomist, I never have the blood lancet to be a more dangerous instrument. There is first the risk of transferring the vein, and then the hazard of wounding the artery beneath it, both the one and the other being greater than with the spring lancet. This latter accident of wounding the artery in the groin or wrist is the median hæmorrhage, is known to be a very rare occurrence in these parts, the

In the first, the blade of one finger, bent at a moderate acute angle, between the thumb and the index, and, drawing the hand over the other three fingers, is so introduced, that the blade is at a right angle with the vessel, and the thumb is at the point of the instrument. Then bringing up the front edge so as to make as firm a pressure as is tolerable in the vein. The operation is then done by drawing the left hand, with which the thumb is pressed, and allows the blood to escape freely, till the amount desired is obtained. The arm is then to be kept in the same position while the blood is escaping, but the other should keep over the surface of the vein, keep the blood from getting dry, and make it coagulate freely and become a solid mass.

When the blood stops, these hands, more pressing direct the patient to move his fingers, so that something round and solid is in his hand. Thus puts the muscles of the arm into action, and the pressure which they then make on the vein makes the blood coagulate most freely through these vessels.

The great quantity of blood being discharged, the flow is to be stopped. The flow of blood now gradually ceases; though sometimes, when the artery is large and the resistance very vigorous, it still continues. In this circumstance, the operator may immediately stop the bleeding, by placing the thumb of his left hand firmly on the vessel, a little below the puncture.

The blood is next to be all wiped off the arm, the sides of the wound placed in contact, and the coagulums applied and secured with a drier, put round the elbow in the form of a figure of 8, and regularly changing just over the coagulums.

The patient should be allowed not to move his arm until the fillet is removed, which may be done after twenty-four hours.

In order to open the external jugular vein, the patient's head is to be laid on one side, and properly supported. Then the operator is to turn open the lower part of the vein with his thumb, so as to make the part above swell, and then the lower is to be pushed at once into the vein, with the canula already armed.

There is commonly no difficulty in stopping the bleeding, after the pressure is removed. Some practitioners divide the instrument with a scalpel, before the vein itself is opened; but this is quite unnecessary. In this country, the fashion of opening the jugular vein has considerably declined. In fact, the operation is now unnecessary, and less certain of success, than elsewhere in the arm; while the principle which recommended the practice is the old saw, namely, that of more effectively discharging, in this manner, blood from the sinuses of the brain, it is erroneous; for it is only the external jugular vein that can be safely opened, and the blood not remove the blood from the sinuses of the head.

Bleeding is in the feet as executed on the same principle as in other parts; but as the blood from the veins in the situation generally does not flow with much energy, it is necessary to immerse the feet in warm water to promote the bleeding.

INTERMITTENT.

The great source of any vein from which blood is withdrawn is, in fact, the trunk and branches of the blood vessel, which in such a situation, that they may easily be compressed against the adjacent bones, and the bleeding stopped. When the vessel which the operator wishes to open lies very near the surface, it may be compressed in drawing, or even by its pressure it may be moved at will with a finger. In many instances it is so deeply situated, that a forceps is necessary in the first place to make a cut in the skin, and then to elevate the vessel.

The blood, however, will not flow very freely, and may have to be continued with a syringe and siphon. As a very low vein, the blood turns itself from side to side, and so it is that it is necessary. When this happens, the coagulums formed, it is recommended to divide the vessel externally across, where it is possible, the process of ligation is done at the end of the vessel, sometimes at a distance below, where it will be traced by the arteries exposed in a dissection. (See Anatomy.) Careful care is to be taken of dividing the vessel and peritoneum.—*Edin. & Camb. Obs. & J. & F. 1821.*

THICKENED SKIN.—PNEUM.

This is done by means of a scarificator, that is a glass shaped somewhat like a bell. The scarificator is an instrument containing a number of lancets, sometimes as many as twenty, which are so contrived that when the instrument is applied to any part of the surface of the body, and a spring is pressed, they suddenly start out and make the necessary punctures. The instrument is so constructed, that the depth to which the lancets penetrate may be made greater or less, at the option of the practitioner. As only small vessels can be thus opened, a very considerable quantity of blood would be discharged, were not some means taken to promote the evacuation. This is commonly done with a sucking glass, the air within the cavity of which is removed by the force of a little long sagging spout of wire, and furnished with a thick wick. This glass is preferable to that of sucking on the top of a glass tipped at the end, and put in the cavity of the leg, as a chimney expedient, adding unnecessarily to the suffering of the patient by confining the skin, doing harm also by carrying the air more than necessary under the glass, in consequence of which the edges of the cup compress the adjacent vessels so much so as to obstruct the influx of blood. The larger the glass, if properly calculated, the less pain does the patient suffer, and the more freely does the blood flow.—(See *Magendie's Treatise on the Art of Dissecting*, p. 62—63, 1826, Lond. 1821.) When the mouth of the glass is placed only the skin, and the scarified area is it becomes condensed as it heats, the glass is forced down to the skin, and a considerable vacuum takes place.

This professor of the said art remarks, that when the operation is about to be done, a basin of warm water, a piece of fine paper, and a lighted candle should be provided. As many of the sucking-glasses as may be judged necessary are to be put in the basin. If sufficient air freely enters of blood too to be taken away, the glasses, if it were adapted to the surface to which they are to be applied, will possibly be required. Each glass must be held for an instant over the place of the operation, and immediately placed upon the skin. Upon the quickness with which this is done, the success and efficacy of the operation will depend. If dry cannot be very injured, the glasses may be allowed to remain on the skin for a few moments, and be raised five or six times, with a little variation of their position, in order to prevent the skin from being hurt by their pressure. If the intention be to scarify and take away blood, the glass should not to remain more than a minute, when the scarificator is to be successively applied; for by the quickness with which the application of the scarificator succeeds the removal of the glass, the patient is saved a degree of pain, which he would otherwise suffer from the making of the punctures. When the glasses are so held as to be in danger of falling off, or the blood is coagulated in them, they should be removed, changed, and applied again. For the sake of success, care should be taken to immerse the end under the upper part of the glass, and remove it so as to keep the bottom downwards, the scarifications being at the same time wiped with a sponge wet in warm water. The glasses also, previously to each application, should be rinsed in warm water, but not dried. For those, and many other kind directions, see *Magendie's Treatise*, p. 64, &c.

There have been made of cylinders calculated for evacuating the air from sucking-glasses; but the glass is not found so convenient as that above described.

A cotton pledget, or bit of rag, is usually applied as a dressing to the punctures made with a scarificator. If a little ointment be not found, Mr. Magendie prefers the application of argemone water or spirits of wine, as it immediately stops the oozing of blood, and prevents subsequent itching.—(P. 63.)

TAPE.

Leeches are often preferable to cupping, when it is needed with very irritable skin, or very sensitive, under particular circumstances, can bear, especially when the topical bleeding is not so frequently repeated, and they can be used in cases in which a wound not so safe or convenient as cupping is required.

Formerly medical leeches were very abundant in England, but owing to their now being in great expense, and to the drawing and absorption of much blood, it is necessary to import large supplies from the

lines up and down the arm, and upon pressing in the course of this part, its degree is increased. On examining the arm attentively, indurated abscesses may be plainly felt, lying in the tumour at the side of the deeper muscle.

The pain and swelling often extend to the axilla, where the glands also sometimes enlarge. Cord-like abscesses, evidently abscesses, may sometimes be felt, and only leaving from the parietes to the axilla in the middle of the arm, but also from this latter situation up to the axillary glands, and from the wound in the arm down to the enlarged glands at the mid-space between the elbow and wrist, over the flexor tendons of the hand.

The enlarged glands often proceed to suppuration, and the patient suffers terrible symptoms. It may be supposed that the foregoing consequences arise from the blood being withdrawn, and from the absorption of the current matter; but the frequent descent of the disease to the inferior abscesses militates against this supposition.

When the abscesses become inflamed, they quickly supersede the effects on the surrounding cellular membrane. These vessels, when indurated, appear like small cords; perhaps of one-sixth of an inch in diameter—the substance causing the slender sides of the vessels, suddenly increased in bulk, but an induration of the surrounding cellular substance.

The inflammation of the abscesses, in consequence of blood being withdrawn from two causes:—the absorption of circulating matter, and the other, the effect of the same irritation on the divided tissue. When vascular matter is taken up by the absorbents, it is generally conveyed to the real absorbent gland, where its progress being retarded, its circulating qualities give rise to inflammation, heat, frequency, an evident distension of the vessel through which it has passed can be distinguished.

When inflammation of the abscesses happens, in consequence of attrition, this part of the vessel nearest the irritating cause generally suffers most, while the glands, being usually drained, and not so much inflamed.

The treatment of the preceding case consists in keeping the arm perfectly quiet in a sling, drawing the parietes of the vein with any suitable adre, covering the section of the inflamed lymphatics with lint wet with the nitrate lotion, and giving some gently purging medicines.

When the glandular swellings suppurate, poultices should be applied, and if the matter does not soon spontaneously make its way outwardly, the surgeon may open the abscess.—(See *Mr. Hunter's Reports on this subject*.)

4. Inflammation of the Vein.

When the vessel does not unite, the vein itself is very likely to inflame. This affection will vary in its degree, extent, and progress. One degree of inflammation may only cause a slight thickening of the vessel tube, and an adhesion of its sides. Abscesses, more or less extensive, may result from an inflammation of greater violence, and the matter may sometimes become blended with the circulating fluids, and produce dangerous consequences; or the matter may be quite absorbed, and make its way to the surface. When the vein is extensively inflamed, a great deal of suppuration does not always ensue, not merely from the effluence which inflammation usually produces, but also from the attrition continued along the membrane being of the vein towards the heart. If, however, the vessel inflammation should fortunately produce an adhesion of the sides of the vein in such order as some little distance from the wounded part, this adhesion will form a boundary to the inflammation, and prevent its spreading farther. The effect of the adhesion is inflammation, in preventing the extension of inflammation along the venous surface, true originally explained by Mr. Hunter. In one case Mr. Hunter applied a compress to the inflamed vein, above the wounded part, and he thought that he had tried succeeded in producing an adhesion, as the inflammation was prevented from spreading further. When the inflammation does not continue rapidly in both directions, but becomes a ring the degree of the vein, its extension in the other direction is probably prevented by the adhesion of the sides of the vein to each other.—(See *Obs.*

on the inflammation of the internal coats of Veins, in *Thomson's A Treatise on the Improvement of Med. and Chir. Knowledge*, vol. I, p. 18, 19.) More information on this subject will be found under the head of Veins.

Mr. Abernethy sometimes has having seen only three cases in which an inflammation of the vein succeeded amputation. In neither of these did the vein suppurate. In one about three inches of the vessel tube inflamed, both above and below the parietes. The inflammations over the vessel were very much swollen, red, and painful, and there was a good deal of fever, with a rapid pulse and limited tongue. The vein did not swell when compressed above the diseased part. In another instance, the inflammation of the vein did not extend towards the heart, but only downwards, in which direction it extended as far as the wrist.

The treatment is to lessen the inflammation of the vein by the same means which other inflammations require, and to keep the attrition from spreading along the contiguous surface of the vessel towards the heart, by placing a compress over the vein a little way above the parietes, in order to make the opposite sides of the vessel adhere together.

Mr. Abernethy describes a case possible in which the vein was very much enlarged, and a total division of the vessel being made, not nearly so elastic the extension of the vessel was, but it present the pain from burning arising with the contraction. Were such a proceeding desired, I think Mr. Hunter's method of stitching the vessel would be best. However, I have never heard of any case in which the practice has been adopted. As for the effects of tying the vein above the diseased part of it, the severe effects frequently following this method treat, as Mr. Hunter has remarked me, render it less eligible than an operation. In the case of an inflamed vein, Dr. Carpman states that nothing is so efficacious as blisters, a practice said to have been first suggested by Mr. Physick.—(See *Effect of an Inflammation of the vein from Fracture*, in *Philadelphia Journal*, Feb. 1811.) I was lately favoured by Mr. Harshby with a view of the state of the parts in a case where a lady had died after an inflammation of the vein of the arm, brought on by venesection: they were considerably thickened, and in some cases quite solid and imperious.—(See *Veins*.)

5. Inflammation of the Paries of the Veins, or slight inflammation of the cellular membrane.

Separation, in consequence of the inflammation arising from the wound of the artery in bleeding, the arm becomes very painful, and soon hardly to move. The parietes often remain thickened, but without much inflammation of the surrounding integuments. The forearm and fingers cannot be extended without great pain. The integuments are sometimes affected with a kind of erysipelas; being not very painful when slightly touched, but when forcibly compressed, so as to affect the inferior parts, the patient suffers a good deal. The pain frequently extends towards the axilla and shoulder; an swelling, however, being powerful in either direction. These symptoms are attended with considerable fever. After about a week, a small superficial collection of matter sometimes takes place a little below the internal condyle; this being opened, a very little pus is discharged, and there is scarcely any diminution of the swelling of pain. Perhaps, after a few days more, a fluctuation of matter is distinguished below the external condyle; and this abscess being opened, a great deal of matter issues from the wound, the swelling greatly subsides, and the patient's future sufferings are comparatively small.

The last opening, however, is often inadequate to the completed discharge of the matter, which is sometimes originally formed beneath the fascia, in the centre of the arm, and its pointing in the upper part of the arm depends on the thickness of the fascia in this situation. The collection of pus descends under the lower part of the detached fascia, and a depending opening for its discharge becomes necessary. This being made, the patient soon gets well.

In these cases the vein is not inflamed; but sometimes the glands of the armpit and pain above the elbow swell. The integuments are not much affected, and the patient complains of a tightness of the forearm. Matter does not always form, and the pliability of the arm after a good while gradually resumes again.

Mr. Wilson relates a case which was followed by a

published what had been communicated to him upon this subject. In the year 1554, Américo Vesputio published a treatise, in which he refers to several witnesses to prove, that the empirical practitioners above alluded to, had learned from him the use of leeches, while, on the other hand, he manifestly avers, that he himself was indebted to Aesculapius, or *Asclepiades*, for a knowledge of those instruments. In 1559, however, Alph. Ferris of Naples, endeavored to show, that his acquaintance with the utility of leeches resulted on the back in 1548, and, of course, that he had anticipated Linnæus, and probably even Aesculapius. But, instead of representing himself as the original inventor of leeches, he manifestly, that they were known to Aesculapius at least 1500 years, if not, carries back the invention to the sixth century. A. Ferris also makes various modes of expressing the state of the system, and, among other things, exhibits three kinds of double lead seal of different sizes. Eschylus's ornaments or seal were round, according to the opinion, and language, were also not used by Pothorius in 1515, and afterwards by A. Ferris. The oldest leeches, which were seals of copper or silver, seemed with some and exclusive patients, were in time succeeded by those composed of brass united with wax. This system was made with the view of letting them have a longer continuation; an experiment which was first tried by Pothorius at Aquapendente. — (M. Chr. 1617.)

In the middle of the 19th century, the manner of thinking and seeing images was well known to Rodin. As a sculptor from the Romanticism era, he

[illegible]

During the course of the other writers, highlighted the efficiency of their designs to the corresponding trend in economic theory. In the economy, the theory of the firm, it was mainly used in the process of production, even when the affected part, and the other, which is that it is possible to have different competitive responses, which is not the case in the theory of the firm, it is possible that it does not have any particular efficiency in the theory of the firm, but by means of some of the other writers, especially the mechanical form.

As the tendency as well as the discussed parts are exposed to the efforts of insects made always active insects, modern surgeons always prefer such an operation made of a sterile and inflexible composition.

Punch recommended bougie of silver, which may be easily introduced into the urethra, even when it is greatly contracted, their size being small. Their introduction, first, and tolerable by insertion. It is almost to insert, however, that it sometimes is applied to the stricture, and gives great pain on being withdrawn. Fortunately, catheter bougies were afterwards used, and the stricture gave a valuable material, on which I did not dwell.

The invention of elastic dentures was rather haphazardly formed, a serendipity at that time in the year 1779 presented some instruments of this kind to the Academy of Surgery, which served as the origin of the claims made by Professor Perrot of Strasbourg, the discoverer. — *Opus Dentale* M.D. 1784.

For the country of England, where there is no thought to be very desirable, as it seems known and inevitable. Mr. Williams, in his *Philosophy of Language*, is inclined to think that the art of doing things (instrumental) is the only one that is really valuable. He says: "The only thing that is really valuable is the art of doing things. The only thing that is really valuable is the art of doing things. The only thing that is really valuable is the art of doing things." This is a very interesting statement, and it is one that is worth considering. It is a statement that is worth considering, and it is one that is worth considering.

I find it positively asserted, however, in a number of great papers, that the idea of making printing the sole office really important in a country, as a national need is nothing more than based on time for a considerable time, and used as a vehicle for oil, linen, or cotton fibre.—*Eng. Lit. for March 1861* (p. 104).

Very clean and good plastic gear boxes as used by Fujiwara, No. 6. Use of this, at least, has a twelve-to-one ratio. His electric gear train is also well made, though for smoothness and speed I think they are not equal to some which we have constructed at London; but I believe Fujiwara's design is rather less than any which are made in this; no advantage which no doubt we are as soon be able to give their production. The same machine does not employ oil in the bearings of the electric gear box, but it is not so well made. These engines are most excellent when you can get them to go; for they show the greatest fire in their possible condition. But engines are not to be appreciated when a gear train can be made which I have made of these I think this comes from their elasticity and inability to become straight when you need the pressure, so that the point presents a certain amount of the stretch. Hence, when the elasticity is in this side, it must be very difficult to get the rest of the train straight.

[illegible]

The device, with its applications, says McHrone, perhaps one of the greatest improvements in

Brachocle is not confined to Europe; it is just such in almost every country on the globe. Professor Burton, in his travels among the Indians north of Mexico in the state of New-York, saw the complaint in an old woman, the wife of the chief of that tribe. When this woman Burton learned that brachocle was by no means unknown among the Ojibwa Indians, the complaint existing in several of their villages. He found also that the disease resembled that seen in Europe, its progress in its varieties. He did not indeed himself see the paroxysms brachocle which descend over the breast; but he understood that it was not uncommon among the women on the banks of the Mohawk river, who were a particular den of its prevalence. In North America brachocle attacks persons of every age; but it is most frequently seen in adults; it differs from what is noticed in Europe. Brachocle is said to be frequent in Lower Canada. Eschscholtz, the companion of Humboldt, informed Albert that the disease was common in New Granada, and that it presented in such a degree in the little spots of Rucala and Narya, on the banks of the Magdalena river, that scarcely any of the inhabitants were free from it. The blacks and those who led an active, vigorous life, however, are reported to escape the complaint. Some of the natives of the influence of El Niño are said to be terribly distressed by it.—(Albert, *Nord. Nat. t. 1, p. 109*, also *Observations sur quelques pleurodynies peu communes pectore* in *globe pour les tropiques, d'après les plantes et les fleurs des Andes par A. de Humboldt, in *Annales de Physiologie par K. Magnus, t. 1, p. 109, Paris, 1824*.)*

In European women brachocle usually makes its appearance at an early age, usually between the eighth and twelfth year, and it continues to increase gradually for three, four, or five years, and is said sometimes to enlarge more during the last half year than for a year or two previously. It does not generally rise so high as the cap, as in the cases mentioned by Wiseman. Sometimes, however, this happens, as we see in the case of Constant Desnoes, of whom Albert has given an engraving. In this patient, a part of the tumor, as large as a hen's egg, projected into the mouth.—(*Nord. Nat. t. 1, p. 406*.) The swelling extended from the ears to the middle of the breast. A tumor produced a partial subsidence of it; but when it was withdrawn the tumor stood. After two years more, the swelling became painful, suppurated, broke place, and effused parts of matter were discharged; and six weeks every day after the swelling had subsided, came away with the dressings for three months; but notwithstanding all this suppuration, and more afterward, the tumor was only partially lessened. The disease, mostly like a pneumonia, firm, not soft, as Albert says, the flap or decay of a turkey-cock, the tumor being the largest part of the breast. Albert mentions a case in which the swelling hung down to the middle of the uterus, and the large mass, which was quite a tumor tumor patient, used to become hard and, as it were, frozen in very cold weather. This action, however, cannot be right, when he adds, that it was in part soft, distensible of elasticity.—(*Nord. Nat. t. 1, p. 406*.) In another curious instance, the tumor formed a long column which reached down to the middle of the thigh, the diameter becoming gradually smaller downwards.—(*Id.* 408.) The treatment of brachocle is the typical gland; but frequently the surrounding cellular membrane is more or less thickened, and constitutes the swelling. Sometimes also the neighboring lymphatic vessels are affected, when it is without and extends from one side of the neck to the other. In these circumstances, the swelling gradually increases itself as the surrounding parts, and is not compressible as an ordinary tumor.—(*Practical Medicine, 1824, 1825, 1826, 1827, 1828, p. 29*.) It is said, or rather before to the neck, and is much at intervals; but after a year, when it has ceased enlarging, it becomes firmer and more fixed. When the disease is very large, a generally moderate difficulty of breathing, which is increased by the patient's walking and or attempting to run. It seems to exert the pressure is so large, and affects the breathing so much, that almost what is mentioned; but there are many exceptions to this remark. Sometimes when the swelling is of great size, persons suffer very little inconvenience; great others are greatly oppressed, though the tumor is small. In general the immobility is

trivial. The voice is sometimes rendered hoarse, and is particularly easy the facility of speech is very considerable.—(*John Hunter, Colles, 1788, t. 2, p. 511*.)

The difficulty of respiration, produced by the pressure of the tumor and the enlargement of other glands, as this disease attacks, is the most dangerous effect of the tumor, since by disordering the pulmonary circulation, it renders the pulse irregular and intermittent, and a strong throbbing is excited in the region of the heart, followed by fatal disease of the lungs themselves; consequences often not supposed to have any connection with the brachocle, though it is in reality the immediate cause of them.—(*Vol. cit. p. 258*.)

The species of brachocle are little known. To the doctrine that brachocle is caused by the earthy impregnation of water used for drink, the following objections offer themselves: 1. The water of Denmark, in districts where this disease is considered endemic, contains much superabundance of lime; but that is opinion too about Nottingham, where the disease is also prevalent, is impregnated with sulphate of lime. However, that the disease is not produced by water impregnated by sulphate of lime is evident; for, as Albert observes, the waters of Saint Jean, Saint Ewald, and Saint Pierre, where brachocle is frequent, contain much less of this earth than the waters of Tignes, Montreux, where the disease is hardly ever noticed, though the lakes are built upon a vast quarry of gypsum. The same fact was observed by Bequaert in New Granada.—(*Nord. Nat. t. 1, p. 411*.) Nor, as Fournier explained, can the cause of the disease be correctly referred to the use of any particular kind of food. Certain localities, however, seem to contribute to its frequency; for the author observes, that the disease is not prevalent in very high places nor in open places; but that it becomes more and more common as we descend into deep valleys made by torrents. Where there is a good deal of marsh, and abundance of fruit-trees. The air is here usually humid. 2. Abstinence from unboiled water does not diminish or interrupt the gradual progress of the disease. 3. Patients are cured of the disease, who still continue to drink water from the same source as before, without making any pretension, as looking, &c. 4. The disease in this country is true frequently found among men. 5. Many instances may be cited of a swelling in the neck, sometimes very painful, and generally termed brachocle, being cured very readily, by difficult partition, violent suction, or any other unusually powerful effort.—(*See Edin. Med. and Surgical Journ. vol. 4, p. 253*.) When the gland is suddenly enlarged during a violent exertion, the disease is said to be produced by the passage of air from the trachea into the substance of the thyroid gland and surrounding cellular membrane. But whether this statement be a fact or not, it is unquestionably true, that in many patients the tumor always increases when they speak loud, sing, or make any effort.—(*Practical Medicine, 1824, t. 1, p. 411*; and *Practical Medicine, p. 54*.) The disease is sometimes seen in scrofulous subjects; but there is every reason to believe that it is quite independent of the other diseases, as Pott, Whistler, and Keatinge have particularly explained. The following are some points of difference between brachocle and scrofula, as indicated by Dr. Pott: 1. The true brachocle is simply a local disease of the neck, the surrounding being unaffected. In the contrary, scrofula extends its efforts to the whole system, attacking not only the lymphatic glands, but also the trachea, cellular parts, bones, ligaments, cartilages, and bones. 2. Scrofula is rarely cured by any agents; but brachocle often begins at a later age than scrofula, and does not, like the latter, spontaneously diminish as the patient grows older, and gains strength. 3. Scrofula is glandular, and separates and discharges, brachocle rarely separates these changes. 4. The histology of the upper lip of scrofulous subjects is not an indication of brachocle. And while the former patients generally enjoy these morbid faculties in perfection as long as they live, the latter disease in certain countries is distinguished with certainty. Scrofula is likewise always hereditary, while brachocle is not so, as healthy persons become scrofulous by living a long while among scrofulous parents, but rarely inheritive contract brachocle by going from a country where this disease is unknown, and taking up their residence in places where it abounds. 5. Nature does often cure

areola, while air is rarely successful; as the contrary, bronchocele is seldom cured by nature, but very frequently by art. The nature of this disease is described by Forster for the case of areola, is always tubercular; but in bronchocele it proves a valuable remedy.—(Pontioli, *Mineralogia della Svizzera del Grigione*, &c. p. 25.) The state of combustion in bronchocele with areola is now generally acknowledged. At the Hospital St. Louis, says Albert, areola presents areolae, while those with bronchocele are very rare. (*Nouvel. Nat. t. 1, p. 165*.) In Derbyshire, Greece, and Piedmont, bronchocele has been noticed in drinking water cool with ice. To this theory many of the opinions concerning the earthy impurities of water stand in full force; with this additional reflection, that the French, where snow-water is commonly used, have usually areolae, and not much with ice, says Wilson; and fewer areolae of them in Switzerland, where we have higher mountains and more snow than in Derbyshire, is well known; they are very common. But when pass the matter beyond a doubt is, that these were areolae in Piedmont, where there is no snow during any part of the year.—(Wilson's *Chemical Essays*, vol. 2, p. 157.) The above opinion was also refuted by Bader, who remarks that the Swiss areolae at the bottom of the glaciers are the most subject to the disease. Bronchocele is also said to be taken in England.

Regarding the influence of particular water in bringing on the disease, Dr. Oiler gives credit to the opinion, because it has appeared to him that distilled water prevented the increase of the disease, and even tended to lessen its bulk.—(*Journal Médical de la Faculté de Médecine de Paris*, 1806, t. 1, p. 101.) However, that every explanation, without exception, is fully proved by the observations of the celebrated Hahnemann. Persons afflicted with bronchocele (the areolae) are met with in the lower course of the Rhodanus river (from Honds to the confins of the Cava); in the upper part of its course (between Nyon and Honds); and on the flat high country of Bugey, six thousand feet above the bed of the river. The first of these three regions is a thick forest, while the second and third present a not dissimilar vegetation; the first and third are exceedingly damp, the second is peculiarly dry; in the second and third regions, the winds are equinoctial; in the first the air is stagnant. To these striking differences, we will add those relative to temperature. In the first and second regions, the thermometer runs up all the year between 51 and 52 rectifigree degrees; in the third, between 1 and 17 degrees. The waters drunk by the inhabitants of Marignat, Honds, and Bugey, are all good, where bronchocele never, or not often of areolae, and hence from rocks of granite and lime. The temperature of the waters of Bugey is and Nyon, drunk by those who have this disease, varies from nine to ten degrees. Bronchocele is the most frequent at Marignat, where the opinion which they offer grants are, according to our experiments, climatically more pure than those of Honds and Bugey, and where the climate is much less airy, than upon the banks of the Rhodanus river. Perhaps it may be thought that the state of the physical system (?) depends less upon the absolute temperature than upon the smaller refrigeration of the atmosphere, the difference of temperature in the night and day; but in the Rhodanus valley, where the coldness of low tropical regions prevails, the extent of the scale that the thermometer presents in the course of the whole year, is only a small number of degrees, &c.—(Hahnemann, in *Journal de Psychologie*, par J. Magon, p. 4, p. 188.)

The same distinguished observer confirms previous accounts of the variety of bronchocele under the original copper-colored natives of America and regions. It appears, also, that in South America bronchocele is progressively extending itself from the lower provinces to the distant regions of the Cordilleras; and this is no minor a degree less in fact the subject was affirmed to be a report sent to Congress by St. Rodriguez, one of the Colombian ministers.

An observation lately made by an intelligent writer would lead one to conclude, that system depends upon penetration of the land. Speaking of gales, as it appears among the inhabitants of the valley of Marignat, Bader formerly informed us, that in many of the cases this is the effect of deficiency in the

of the crusts, of which the smallness and narrowness of the areolae are especially remarkable.—(Mém. de Chén, *Mém. t. 1, p. 121*.) Dr. Costa thinks that remains of this sort may be owing to the severity of the cold damp air, as they generally appear in winter, and finally clear in the warm dry climates of Italy and Portugal. The latter part of the observation, however, is not correct, for that, Portugal, and other Italian writers, signify that the disease is extremely common in some of the watery parts of Italy. "Qua in Napoli, per tutto il corso, di stagione, non essendo mai in unione, che, come in Canada, ed in pochi altri luoghi."—(P. 21.) Prætor is inclined to consider the bronchocele as a kind of trophy of the thyroid gland, similar to the trophy of the ovary; and he mentions that Dr. Hanger discovered one thyroid gland which had been considerably enlarged, and contained many cysts filled with water. These, he erroneously concludes, must have been hydatids. Dr. Bader remarks, that which a tumor is made of the thyroid gland affected with this disease, the part is found to consist of a number of cells containing a transparent fluid fat.

In all probability the ordinary bronchocele is entirely a local disease; patients usually finding themselves in other respects perfectly well. The tumor itself frequently assumes to some extent the incompressible, and is only a deficiency. There is no malignancy in the disease, and the swelling is not prone to increase or suppurate, though, as Dr. Hanger remarks, abscesses do occasionally form in it. Although some of bronchocele becoming cancerous is singular. Mr. Good never knew life to be endangered by this sort of cancer, however large; a remark very much at variance with the observations of some other practitioners; but he had never given incision, as he thought it was not indicated with safety. In fact, the pressure of a large bronchocele may not only greatly affect the patient, by rendering respiration difficult, but actually cause death by asphyxiation.—(See also, our own observations, *congruente in Thèse de Médecine*, par J. Hénault, in *Bulletin de l'Académie de Médecine*, &c.) Some persons, as Albert remarks, have the disease all their lives without suffering any inconvenience from it; some experience a suffocating oppression at the breathing; and in others there is an impediment in the circulation, and a tendency to suppurate, arising from the stimulation which afflicts them.—(Nouvel. Nat. t. 1, p. 166.) Dr. Hanger says, that the bronchocele frequently appears two or three years before it affects the commencement of menstruation, and that it sometimes spontaneously disappears, when this cessation goes on in a regular manner. Mr. A. Burns affirms the same thing. On the contrary, according to Proust, this change in the constitution hardly ever affects the tumor.

TREATMENT OF BRONCHOCELE.

That certain localities, perhaps not yet correctly ascertained, contribute to the origin of this disease, is well proved by a fact stated by Albert, viz. that change of air has more effect on the complaint than incision, as he has known many Swiss ladies who came to Paris with bronchocele, in whom the tumor subsided after they had resided some time at that city.—(Nouvel. Nat. t. 1, p. 172.)

A blister kept open, has put a stop to the growth of the tumor; but this method is not much followed at present, as better plans of treatment have been discovered. A few years ago the discovery made of curing bronchocele consisted in giving internally burnt sponge, and occasionally a calomel purge, at the same time that friction was made upon the tumor itself. The utility of burnt sponge is the treatment of bronchocele, as Dr. Comber and others have now fully proved, depends upon the iodine in its composition.

The efficacy of burnt sponge was thought to be greatest, when exhibited in the form of a lozenge composed of tincture of the substance, but of burnt cork, and the same quantity of pulvis-stone. These lozenges were made into the proper form with a little sugar, and the lozenges were then put under the tongue and allowed to dissolve. To the latter circumstance much importance was attached. Some practitioners gave a large quantity of burnt sponge about three or four times a day, while others added a grain of calomel to each dose. A purge of calomel was ordered about once a week or fortnight, as long as the patient persevered in the use of the calomel sponge; but when mercury was continued 9 or 12

with dose of this medicine, no economical purgative was deemed requisite.

External means only very externally assist the above internal remedies. Frequently rubbing the swelling with a dry towel, bathing the part with cold water, rubbing the tumour two or three times a day with the oil, arsenic, &c., is the domestic treatment; and the best usage of this kind which the surgeon can take.

"In the treatment of bronchocele," says Mr. A. Farre, "a repeated topical extraction of blood from the tumour is highly beneficial. Externally also, but sometimes a marked effect; but there is no remedy which I would more strongly advise, than regularly and long-continued friction over the tumour. My perseverance in this plan, a bronchocele, treated in London, was materially relieved in the course of six weeks. Its good effects I have likewise witnessed myself; and it is a remedy highly recommended by Goussier in his 'Étude des Goitres.' It has also been much used in scrophulous tumours by Mr. Goussier, of Orléans, and by Mr. Russell of Edinburgh."—(*English Anatomy of the Head and Neck*, p. 294.)

Mr. A. Farre recommends the friction to be made with dressed linseed, with four ounces, being the part to be rubbed at least three times a day, for twenty months.

In two cases of bronchocele related by Mr. Clarke, the patients were cured by "the merely use of the compound plaster of ammoniac and mercury, composed with the internal exhibition of burnt sponge and medicinal purgatives."—(*See Eng. Med. and Surg. Journal*, vol. 4, p. 294.)

We learn from Professor Ollier, that, in Geneva, bronchocele used to be cured by burnt sponge withlaid in powder or infused in wine, and combined with purgatives to prevent the escape of the mercury, which sometimes accompany the absorption of the swelling. Muriate of barytes has likewise been recommended.—(*See Manuel de Médecine Pratique*.)

Mr. Wilmer, considerably improving upon Ollier, in the changes of the tumor, used to begin with six scruples the day after the full moon, and to give a pill the evening day. The night following and seven nights successively he dropped the above-mentioned liniment to be put under the tongue at bedtime, and administered every room a better tolerable powder. On the eighth day the purge was repeated, and in the case of the succeeding ones, the whole process, except the emetic, was renewed.—(*Cases in Surgery*, Appendix.) This, which is often called the Coventry plan of treatment, is said to be greatly assisted by rubbing the tumor with an ointment containing hen's egg.

Prosser succeeded with his patients, though the patient was twenty-two years old, and the swelling had existed more than twelve years. It is said that no instance of cure has been known after the patient was twenty-five. Prosser orders one of the following projects to be taken early in the morning, an hour or two after breakfast and at five or six weeks in the evening, every day, for a fortnight or three weeks. The powder may be taken in a little syrup or sugar and water; R. Camph. and op. levigated, each ʒij. of pulp. ʒij. gr. ss. M. ʒij. of oil. ʒij. ʒij.

Three powders should be taken for two or three weeks, and then left for a week or nine days before a repetition. At bedtime every night, during the second course of the powder, some purgative pills composed of mercury, the curative colic, castor, rose, and rhubarb, are to be administered; and in general it will be proper to purge the patient with opium or salts, before beginning with the powder. Prosser put his faith in external applications.

Some have recommended giving two scruples of colored sugar daily every morning, in a glass of red wine; half a drachm of the sulphate of potash every day dissolved in water; or ten or fifteen drops of the third spirit, twice a day, the dose being gradually increased. Muriate of barytes, &c., and belladonna have also been advised. Podagrace commends the mixture of tar as a remedy in producing great effects. The remedy is said to be taken with honey, so which is sometimes added burnt sponge, with camphor in powder. He employs also decoction with flaxseed, linseed, and sometimes gargar with calomel. The tumor is placed under the tongue, and allowed to dissolve slowly.—(*P. 26, 27*.)

Dr. W. W. physician to the emperor of Russia, prescribes three grains of the sublimate of mercury,

dose of the anhydrous trisalt of iron, four of burnt sponge, and ten of the bark of *Quercus*, divided in a treble dose, one of which is given twice a week with a gentle laxative at night. He also directs twenty-four leeches to be made, by introducing an ounce of burnt sponge with an equal quantity of the powder of quercus, and fifteen grains of castor-oil, first blended with a sufficient quantity of the spirit of camphor. One of these leeches is put under the tongue daily and allowed to dissolve there. Lastly, to the tumor itself he applies a plaster composed of half an ounce of sulphur, a drachm of the sublimate of mercury, and 33 grains of arsen. tartar.—(*J. Allier, Nouv. Jour. de M. p. 374*.)

The nature of burnt sponge in the cure of certain forms of bronchocele was first ascertained to be owing to the iodine which it contains. Iodine was discovered in 1812 by Courcier, superintendent of salt-pans at Paris; but six years elapsed before it was tried as a medicine. From the first meeting of Dr. Couderc, witnessed in 1818 in the Helvetic Society of Natural Sciences, it appears, that as he was searching for a formula in the work of Calot de Goussier, he found that Couderc had recommended the ashes of the *Juncea viscaria*, or *Sedum viscaria*, under the name of *sedum viscaria*, for the cure of bronchocele; and he was led from analogy between this substance and burnt sponge, so long celebrated for its efficacy in the treatment of bronchocele, to suspect that iodine was the active principle of both. "The great and unexpected success which resulted from its use in the treatment of bronchocele, it once revealed the power of iodine as a therapeutic agent, and encouraged Dr. Couderc to pursue his researches in endeavoring to ascertain the nature of the materia medica; and about the close of the same year, when Dr. Couderc had employed iodine in treating piles for six months at least, his conjecture was confirmed by the discovery which Dr. Fyfe of Edinburgh made, that this substance was actually contained in the ashes of the burnt sponge." &c.

"It has been generally understood among the physicians, that the happy conjecture which introduced iodine into medical treatment, originated with Dr. Couderc of Geneva; yet we find that his claim to this honor is disputed by one of his countrymen, Dr. J. J. Struth, of Neuchâtel, in the *Archives de Médecine*."

Dr. Struth, whose communication is found in *Prosser's Memoirs of the Helvetic Society of Natural Sciences* for 1820, states, that before the discovery of iodine, attempts had been made to compound a substitute for burnt sponge, but without success, and that this failure and his observation of the similarity of smell between iodine, burnt sponge, and other marine productions, led him to suspect the existence of iodine or its salts in these substances, and that he observed in the artificial compound was the cause of failure in those experiments. This conjecture, which appears to have been made previously to 1817, led Dr. Struth to examine the real burnt sponge, and to inform us, that though his time did not permit him to ascertain exact quantities, yet he obtained from 15 gr. of burnt sponge an ounce of iodine as to render his conjecture probable, and to be ascertained that the agent that should have escaped notice. He was therefore at once induced to think of its use in medicine; and in the same paper from which we derive these facts, improved with the poisonous quality ascribed by Deleuze to iodine, he recommended first the trial of its salts, especially the hydroiodate of soda and lime, and that that of the substance itself.

The communication of Dr. Struth is dated Dec. 1818, and was actually published in *Prosser's Memoirs* in the periodical work in February, 1820, two months at least before the first meeting of the Couderc, was communicated to the Helvetic Society of Natural Sciences at Geneva. It is unnecessary to insist on the force of any supposition of iodine dose to Dr. Struth; which has led to it in right to deprive Dr. Couderc of the merit of originality in ascertaining the direct and certain action of iodine, on the irregular and sometimes local qualities of burnt sponge in the treatment of piles. Consideration of this kind is not uncommon in science; in the present instance, the superiority of Dr. Struth does not diminish the merit of Dr. Couderc.—(*See Eng. Med. and Surg. Journal*, N. 85, p. 210, &c.)

That iodine is a medicine of considerable efficacy in

Academy of Surgery at Paris, in which the disease had been got rid of either by means of a seton, drawn through the swelling, or the application of an issue.—(*Revue Méd. et Chir. Paris*, 1775.) The successful removal of setons was also adverted to by Richter in the year 1780.—(*Abhandl.*, 3, 9, p. 478.) And the plan is spoken of in another work, published in 1786, as being eligible where the disease is accompanied with a cyst.—(*Encyclopædie Méthod. par M. Cuv.*, t. 1, p. 231.) The practice was particularly resorted to by Pott in his valuable treatise on aneurysms; and Aldert testifies the success as being met at the Hospital St. Louis.—(*Médec. Nat.*, t. 1, p. 466, *ed. Paris*, 1817.)

In November, 1837, Dr. Blandin, of Naples, tried this practice, which he accordingly supposed to be efficacious. "By means of a bronze-pointed needle six and a half inches long, I passed (page 83) a seton from above downwards through the gland, to the depth of about four lines from its surface. Suppuration took place in forty-eight hours. By the 15th of November, the tumor ceased, when the matter was squeezed out; and the irritation occasioned by replacing it, produced an abscess on the right side of the neck, which was opened on the 23d, when it was found that the suppuration had effected the destruction of nearly the whole gland." The woman, who was thirty-six years of age, was sent by Dr. Blandin, in April, 1838, with the circumference of her neck increased from sixteen to fifteen inches, French measure. In another case referred to, a seton was passed through each side of the thyroid gland, and the result was a removal of the tumor on the side where the seton was maintained long enough; but on the opposite side the seton being withdrawn too early, the tumor collected in a seton, and at the end of four months a discharge still continued, the patient refusing to have a further opening made. When the seton does not prove stimulating enough, Dr. Quain sometimes enlarges it, or attaches to it catarrhic or irritating substances. He also frequently uses two setons. In one example, in endeavoring to perforate the gland rather deeply, Dr. Quain appears to have injured the larger branches of the thyroid arteries, so that there was a source of blood was destroyed, and the tumor swelled as if injected with blood. The bleeding, however, ceased spontaneously. He states that the seton has been passed through the tumor as low as sixteen times, the disease being varied in every instance, without upward ascent; and he is confident, that unless the needle be pushed deep enough almost to touch the thyroid cartilage, the trunks of the thyroid arteries will not be exposed to injury, while the trachea is the track of the needle will not cause any danger. He inserts also upon the propriety of retaining the seton in the tumor a considerable time; and observes, that it remains to be ascertained whether this practice will answer in every description of bronchocele. For these and several other cases and particulars, the profession is indebted to Dr. Sarsville.—(*See Med. Chir. Trans.* vol. 10, p. 16, &c.)

Mr. Gussing applied a seton in a case of bronchocele in St. George's Hospital; but in this instance the irritation brought on sloughing, and the patient after a time died. The particulars of this case, and of three successful examples of the practice in England, have been lately recorded. One of the successful cases was treated by Mr. David M. Jones, of Exeter, brother by Mr. A. C. Hutchinson, who has taken the trouble to collect the history of these, and the third by Dr. A. T. Thomson.—(*See Med. Chir. Trans.* vol. 11, p. 223.) Percy and Desautel have also employed setons in bronchocele with success. The plan, however, is sometimes inefficient, as is proved by two cases under Dr. Keen's, of Glasgow.—(*See London Med. Repository* No. 93, Feb. 1821.) The great source of cases referred to this practice, and their difference from other cases, which are brought by treatment of a different kind, are still doubtful in surgery.

The diseased thyroid gland has been successfully extirpated; but the operation is one of so much danger, that a slight resort to be attempted except under the most pressing circumstances. The most large arteries are usually distributed to the gland itself; their still greater size is bronchocele; and the vicinity of the carotid arteries, and important nerves, render the excising a thing of no common difficulty.

Mr. Gooch relates two cases, which do not engraft

the practitioners to have recourse to the excision of enlarged thyroid glands. In one, we suppose an aneurysm took place, and the surgeon, though usually bold and experienced, was obliged to stop in the middle of the operation. No means resulted in entirely suppressing the bleeding, and the patient died in a few days. In the other, the same event finally took place, the patient's life being saved only by compressing the wounded vessels with the hand, day and night, for a whole week, by persons who relieved each other in turn. This was found the only way of stopping the hemorrhage, after many fruitless attempts to do the same.

Hæmorrhage is not the only risk; Desautel related a large bronchocele that caused dangerous pressure upon the trachea; the whole gland was taken away, and the four thyroid arteries and many veins secured. Only a few apostles of blood were lost. The woman, however, died soon after the operation, was pale, had hurried respiration, cold skin, sickness, and, denoting agony of some important nerve.

I do not mention these facts to deter surgeons from the operation altogether, because it is proved by modern experience, and especially by six cases in which Dr. Hodgson, at Dresden, has successfully removed the thyroid gland, that not only is it occasionally a necessary proceeding, but one that may be well accomplished by a skilful operator, as will be particularly explained in a future article.—(See Thyroid Gland.) When bronchocele by their present dangerous obstructed respiration, deglutition, and the removal of blood from the body; and when the disease reveals the vicinity of trachea, a seton, Hodgson, and every other plan of treatment found deservings of study; what can be done with the view of saving the patient, but the bold operation of cutting away the swelling, or that of exposing and tying one or both of the upper thyroid arteries?

When the quantity of blood flowing into a tumor is suddenly and greatly diminished, the size of the swelling commonly soon undergoes a considerable diminution. The experiment was once made by Mr. W. Hare, in tying the arteries of an enlarged thyroid gland, and, in a week, the tumor was reduced one-third in its size. The ligatures then sloughed off, repeated bleeding took place from the arteries, and by the extension of tracheal compression, the carotid itself was exposed. The patient died; yet, as Mr. A. Burns observes, this does not suffice against a repetition of the experiment; as the same thing might have happened from merely opening a vein, and, in the removal of air of a tumor, has actually happened.—(*Surgical Anatomy of the Head and Neck*, p. 292.)

In fact, the immutability of the experiment prevented surgeons from being introduced by the failure in question; and, with that laudable spirit for the improvement of operative surgery every where diffusing itself through the profession, other gentlemen were soon found who had judgment enough to make further trial of the practice. In a young man, twenty-four years of age, whose breathing was much impeded by a bronchocele, and whose upper thyroid arteries were very large, and affected with strong pulsations, Wither, of Leeds, tied the left of these vessels, the left side of the gland being the largest. The operation was done on the 24 of June, 1814. An incision, an inch and a half in length, was made in the direction of the lower edge of the sternum-musculo-sternal muscle, where the throbbing of the artery was quite distinct. By a second stroke of the knife, the playmate *arteria* was divided at the same distance, and to an equal extent. The vessel was then exposed by a careful dissection, and separated from the surrounding parts, and one arterial branch which was divided was immediately secured. A ligature composed of three silk threads, was then applied with an American handle, under the left thyroid artery, and tied with three simple knots. The wound was then closed with adhesive plaster, and the ends of the ligatures brought out at the angles. The ligature on the large artery gave energy on the 15th day; and, without any febrile symptoms, or other bad consequences, the wound was perfectly healed on the 25th day. As early as the third day after the application of the ligature, the left part of the tumor began to be less tense, and the throbbing less as it soon ceased. By degrees it diminished away, becoming as it lessened harder and, as it were, cartilaginous. In a

fortnight, the left half of the swelling was one-third smaller than before the operation; and, in length, only one-third of it remained, while the right side also was somewhat smaller. On the 17th of June, Weather took up the right segment of the artery, which was more difficult to get at, as it lay more deeply, and was much encased under the external gland, which had pushed it out of its natural situation. The operation lasted three-quarters of an hour, and several large and small arteries which were cut were tied. With respect to the thyroid artery itself, it could not be tied without bleeding a part of the gland in the incision. No satisfactory spasmatics followed the second operation; the ligatures were detached in good time, and the wound healed very well. The right portion of the bronchocele also now disappeared; but though it was certainly smaller than the left, it did not entirely relax so completely as the latter. The result of the operation, however, three years afterward, produced no inconvenience, and resembled the quiet way—(See *New Bedford der Kregein*, &c. vol. IV. p. 10. and *Walters*, p. 15. &c. New York, 1871.) On the 21st of December, 1853, Mr. H. Collins of Philadelphia, took up the superior thyroid artery for the cure of a bronchocele, which, in a young woman aged seventeen, had pressure on the trachea and oesophagus, attended with a great degree of swelling. The superior thyroid artery was in this instance large and pulsated strongly. Mr. Collins cut down upon the left of these vessels, separated it from its accompanying artery, and passed under it a small round ligature, which was drawn suddenly tight and cut. The next day there was hæmorrhage, and some swelling of the neck and side of the head, with increased difficulty of swallowing and flatulency of the bowels. These complaints, however, were relieved by bleeding and antiseptic medicines. The ligature came away on the 5th day; and on the 14th, the wound was completely healed. On the 14th of February, the breathing being much improved, and the patient relaxed nearly to quadruple of its former size, the patient was very much to be discharged from the infirmary. (See *Med. Clin. Trans.* vol. III. p. 312.) My friend, Mr. Ross, once mentioned to me a case, in which a similar operation done by Mr. Brooke, did not produce any material diminution of the tumour.

Dr. Parry has remarked a frequent coincidence, either as cause or effect, between enlargement of the thyroid gland and cardiac diseases. (—*Elements of Pathology*, 5th p. 182.) And another modern writer mentions, that he has lately seen three cases of this coincidence. (—*Medico-Chir. Journ.* vol. I. p. 191.) A case is detailed by Flajous, where the disease was accompanied with extreme fatty degeneration of the heart. (—*Soc. Colloquie d'Chirurgie*, &c. 4th Christian, 1. 2, p. 270.) In the instance here referred to, there was great irregularity of the pulse, and the symptoms of the breathing was such, that the patient was obliged to submit to respiration at least every month, whereby he was rendered quite enervated.

The prevalence of goitre in different parts of the U. States is stated by our authors, and several American writers have described the disease as existing in various parts of our country, which produce instances very widely differ in many respects. In Vermont, in New-York, in Pennsylvania and Ohio, the disease is by no means infrequent. Professors Burrow and Gibbon, of Philadelphia, have communicated many valuable observations on this disease. More recently, Professor Francis, of New-York, has made a series of observations of goitre as it appears in the western part of the state of New-York. From the communication with which he has kindly favoured me, the following abstract is given. I may add, that according to the facts deduced from the changes which our country undergoes in the progress of improvement, we have the strongest reasons to believe that as the climate and cultivation are extended, the frequency of the existence of this disease will diminish, become, so to speak, a relic.

However frequent cases of goitre may have formerly been in the state of New-York, the fact is certain, that they are much more rare at present. Even the hyperæmias of the larynx, which Dr. Dwight, relative to the great prevalence of the disease, thought among the most frequent with which we have been favoured, are to be regarded with astonishment. That in particular portions of our western valley popular examples are to be

found, may be known by any accurate observer. But—in the village of Union, (near Dr. Francis's) which contains between 1 and 2000 inhabitants, no case of bronchocele could be pointed out, and this village occupies the site of old Fort Schuyler, on the Mohawk, the vicinity of which has been referred to as the spot where goitre was particularly prevalent. I am strengthened in the accuracy of this statement relative to the almost total disappearance of goitre in this neighbourhood by the testimony of Dr. Coventry. A similar remark may be made with regard to the former frequency of the disease throughout the extensive region from Utica to Buffalo. The late Ulrich Tracy, in his extensive travels this country some years since, was led to believe this bronchocele prevailed in the wilderness as well as in the town, and thought it peculiar to the country of lakes. In my late visit I made special inquiry as to the present condition of the health of the inhabitants, and ascertained that the instances of goitre are nearly none save those in the period of Mr. Tracy's observations. The number of cases which exist under any name during the year were twenty-three. These were at Herkimer, Morris, Syracuse, Oneida, Hamilton, Williamsville, and Buffalo; and I saw none else in the neighbourhood of Buffalo than at any other place. In other parts of the state the disease may be seen, particularly in the county of Albany.

To assign a satisfactory cause for the disease is difficult, perhaps impossible. Dr. Burrow has endeavoured to show that goitre and enlargement and tenderness of the heart have one common origin, and argues this opinion from the simultaneous prevalence of these diseases, from the frequency of glandular affections where malignants abound, and from the opinion that persons afflicted with goitre are exempt from intemperance, though in the midst of these diseases. Dr. Coventry inclines to ascribe it to drinking water impregnated with alum. Dr. Dwight advocates the more recent opinion that these affections originate from the lime contained in the water drunk in those regions. Dr. Francis ascribes the production of the disease chiefly to humidity, and hence it prevails most in the vicinity of lakes and rivers where vegetation abounds. He says, it increases with the rainy seasons, and is diminished when the weather becomes cold and dry, and hence argues the reason of its disappearance as the country becomes drier. He however does not altogether reject the agency of certain waters in aggravating if not producing the disease.

On the 23 cases examined by Dr. Francis, two only were in male subjects, and one of these in adult Indians, in Niagara county. He saw it in an infant but a few months old, and he subscribes to the opinion that it often depends on constitutional causes, and is sometimes hereditary.

In Onondaga county, Dr. Francis learned that goitre prevailed among sheep, and Fodder grew as a regular fact of its hereditary among dogs. The treatment of blisters and others, in considering the several functions connected with this disease, are limited by its greater prevalence among women, and also according to Dr. F. by some well-known facts connected with parturition.

Dr. Coventry has removed several cases of goitre by the simple expedient of the patient wearing the rotation of water about the neck. The recent plan of Mr. Hoffman, of employing steady pressure, has been tried in this country with some success. The efficacy of hard sponge has often been seen; but instances of its being are not infrequent. The iodine has been used of late years with the best effects, and Dr. Congdon, of Buffalo, has reported its cases where it is a number of cases.

Dr. Francis observed one, that in a subsequent journey through this state, he found a number of interesting cases, and that the disease in every instance afflicts the female sex, and in each of these cases it was directly associated with the formation of tumours and polypus. The left lobe of the gland was most frequently the seat of the disease, but in no instance was it connected with cancer. His reports are instances of the cure of a female case which occurred in a young married woman, who, after leaving the neighbourhood of Onondaga and removing to the western state, after a residence of three years, was seriously afflicted of her goitre.

died of asphyxiation. On dissection, no inflammation in the larynx was observed, but only an inflammation of its membrane, and a spot like a small pea pointed upon the margin of the glottis.—(*Foreign Obs.* part 1, p. 18.)

Children sometimes accidentally drink boiling water from the spout of a tea-kettle. The effects of this accident (says Dr. Hall) are not, as might be supposed, a puerile, the symptoms of inflammation of the mucous membrane, but of inflammation of the glands and vessels, resembling those of erysipelas; and the case constitutes another instance, in which the operation of leeches, locally, or of leeches only, may be performed with the effect of procuring suppuration, and perhaps of curing it.—(*Med. Obs. Trans.* vol. 12, p. 2.) The cases and remarks collected by Dr. Hall, Mr. Gilman, and Mr. Stilling are this subject, cannot fail to be highly interesting to practitioners. In a case of the foregoing description, Mr. Wallace, of Dublin, performed tracheotomy with success.—(*See Lond. Med. and Phys. Journ.* for July, 1822.) Mr. Simpson, who has seen five cases, in 1813, looking upon water taken into the trachea, thinks that death, when it follows, is almost always produced by asphyxiated inspiration. In one of the examples which he has recorded, bronchovaginal was the means of saving the child.—(*See British Hospital Reports*, vol. 2.) Great mechanical injury of the larynx, caused by a blow or fall, may even the way to bronchotomy, as is proved by a case lately reported by Mr. Latham.—(*See Ed. N. S. and Surg. Journ.* vol. 16, p. 553.)

There is no inconsiderable diversity of opinion among eminent surgeons as to the propriety of performing tracheotomy in cases of croup, and those who oppose the operation, very justly allege, that in the intermediate stage of croup an advantage can result from the operation, however favourable the condition of the surface may be in other respects. The views of the celebrated Cullen would seem to yet beyond doubt the utility of the operation as already stated, by our author, because it is analogous in its removal of the accidental inflammation which is effused in the advanced stage of croup to the trachea. I am not prepared, from my own experience, wholly to decide the difficulty. We have evidence sufficient, I think, to justify an occasional recourse to this extreme of surgical skill, but there is still another stage of relief, not stated by our author, that may fitly be introduced here, which will often render this operation unnecessary, even in those cases in which it is confidently recommended by some, and certainly ought to be fully tried before we avail ourselves of so doubtful a remedy.

In that stage of croup which has been aptly termed the fatal stage, from its so generally proving such, and which is characterized by the existence of the membrane, the viscous crusts have been introduced with decided success.

This practice was first introduced by Professor Francis, of New-York, in 1812; and since the report of its success, has become very generally adopted in this country, and with singular success. I have now in my possession a specimen of an entire membrane lining the trachea, detached and thrown up under the powerful electric action of the blue vitrol, after venesection, blisters, calomel, purgative, &c. and all the approved remedies had been tried ineffectually.

I regret that the facts assigned do not preclude my presenting an interesting detail of this case reported by Dr. Francis, in his valuable paper published on this subject, and have to content myself with referring to the (*N. Y. Med. and Phys. Journ.* vol. 2, p. 58, of seq. only remarking, that in the latest hopelessly state in which the aspects of asphyxiation are so threatening, relieved, in large doses, as among the most efficient remedies to which we can have recourse. "After the removal of the membrane," observes Dr. F., "and when the progress of life on the lungs, is a judicious and sometimes an available resource," and he adds that in the cases in which he failed the viscous crusts were successful, their agency was probably destroyed by that potent remedial.

I think similar practice has been adopted by Dr. Hoffmann, of Vienna, who first used the viscous crusts in 1820; and so striking does he consider them, that he declares their action to be a specific in this stage of croup. These arguments, saying too much in their behalf, are certainly they are treated in large quantities, and ought never to be omitted in some striking favorable cases.—(*See*.)

2. The compression of the trachea by foreign bodies,

lodged in the pharynx, or by tumours, formed externally, and of sufficient size to compress the windpipe, but not admitting of immediate removal, is an equal reason for operating more or less expediently, according to the symptoms. Mr. B. first mentions two instances of suffocation from bodies falling into the pharynx. Respiration was only stopped for a few minutes; but the cases were equally fatal, notwithstanding the employment of all the usual means. The author thinks that hemorrhage would have been attended with complete success, if it had been performed in time. The operation should also be done, when the trachea is dangerously compressed by tumours. The author of the *Encyclopædie*, observes, in *Encyclopædie Médecine*, says, that about twenty years ago he attended a man, who had had an aneurysm, which came on instantaneously. He had had, for a long while, a breast tumour, which was of an enormous magnitude towards the end of his life. The cavity of the trachea was so obliterated, that there was scarcely room enough to admit the thickness of a small piece of osseous. Doubtless, bronchotomy, performed before the aneurysm made its appearance, might have prolonged that man's days.

In cases of this last description, Denon would have advised the introduction of an elastic gas catheter into the trachea from the nose, in order to facilitate respiration. This practice, I believe, has not hitherto been attempted by English surgeons.—(*See Médecine Clin. de Paris*, t. 2, p. 235, &c.)

Hartree successfully performed this operation on a female seven years old, who, having heard that gold, when swallowed, did no harm, attempted to swallow nine pencils, wrapped up in a piece of cloth, in order to hide them from her father. The pencil, which was very large, could not pass the narrow part of the pharynx, and here it lodged, so that it could neither be extruded nor forced down into the stomach. The boy was in the point of being suffocated by the pressure which the foreign body made on the trachea; and his neck and face were so swollen and black, that he could not have been known. Hartree, in whose house the patient was brought, attempted in vain, by different means, to dislodge the foreign body. At length, perceiving the present an evident danger of being suffocated, he resolved to perform bronchotomy. This operation was however done, thus the swelling and lividity of the face and neck disappeared. Hartree passed the piece of gold down into the stomach with a broken probe, and the pencils were, at different times, discharged from the nose, salt or tea days afterward. The wound of the trachea was healed.—(*See Médec. de l'Acad. de Chirurgie* from 11, p. 312, &c. in *France*.)

In such a case Denon would have introduced an elastic gas catheter into the larynx, instead of performing bronchotomy, which could not answer, yet the foreign body was down.—(*See Chirurgical Anals.* t. 2, p. 247.)

3. Foreign bodies in the trachea may render it necessary to practice bronchotomy. Here I ought not to say, perhaps, laryngotomy, which by several surgeons is deemed most applicable.—(*Quæst.* C. III, Surg. Obs. part 1, p. 67, &c.)

Little is so ancient as the observation on extraneous substances in the trachea, has proved, more successful than all other gooding writers, the necessity of the operation in circumstances of this kind. The following case will render his observation.

On Monday, the 10th of May, 1729, a little girl, seven years of age, playing with some dead lily-buds, threw one into her mouth and thought she had swallowed it. She was immediately attacked with a difficulty of breathing and a severe convulsive cough. The little girl and her mother swallowed a loaf, and such assistance as was thought proper was given, but Ward of success was the cause of several symptoms being successively sent her, who finally employed the different means prescribed by art for extraneous foreign bodies from the œsophagus, or forcing them into the stomach. A life species cautiously inserted to the end of a whalebone probe, was repeatedly introduced through the whole extent of the œsophagus. The little girl, who made a sign with her fingers, that the foreign body was situated in the middle of the neck, thought that she felt some relief when the sponge was conveyed below the place which she pointed out. She had every now and then a violent cough, the efforts attending which produced copious fluids in all her trachea. Duglès

seen was unobstructed; and warm water and oil of sweet almonds had been swallowed without difficulty. Two whole days had been passed in suffrage, when the pulmonary crisis in Louis. The little girl, with all possible fortitude and courage, was several times told in the friends' ears ready to die of suffocation. Louis, when aware of what had happened, came into the room where the patient was. She was sitting up in her bed, suffering no other symptoms than a very great difficulty of breathing. Louis inquired where she felt pain, and she made such a sign in reply, as left no doubt concerning the nature of the accident. She put the index finger of her left hand on the trachea, between the larynx and epiglottis. The friends always which had been made in the epiglottis with a view of discovering the foreign body, the nature and the position of this body, which was not such as would be adapted to the passage for the food; and the facility of swallowing, were negative proofs that the want was not in the oesophagus. Respiration was the only function disturbed; it was attended with difficulty and a rattling in the throat. The little girl expressed a filthy smell, and she pointed out so sensitively the painful point where she coughed, producing all her sufferings were removed, that Louis did not hesitate to deduce from the relations, from this single inspection, that the lesion was in the trachea, and that there was only one way of saving the child's life, which was to make an incision for the purpose of extracting the foreign body. He required then, that the operation was neither difficult nor dangerous, that it had succeeded as often as it had been practiced, and that the very passing danger of the case only just allowed time to him, the opinion of some other well-informed surgeons, respecting the indispensability necessity for such an operation. Louis thought this permission necessary in order to acquire the confidence of the parents, and to shelter himself from all reproach in case the event of the case should not correspond with his hopes. Louis went home to inquire all the requests he transmitted, and in two hours he was informed the surgeons who were consulted waited for him. After Louis was away, his child had become quiet, and was now lying on its side asleep. The opinion he had delivered had been explained by the friends and attendants, and had been discussed before his return. They who had been consulting their associates, on the supposition that the foreign body was in the oesophagus, cannot approve of the proposal of extracting by an operation a substance the presence of which in any part of the body was not obvious. Louis explained his advice in regard to bronchotomy, and did not expect a doubt to be set up against its positive a fact. It was objected, that a substance as large as a bone could not introduce itself into the trachea. He brought every line into his argument by a short explanation of cases of this sort with which he himself was acquainted. The little girl was examined; she was better than when Louis saw her before, and a very palpable emphysema was seen above the clavicle on each side of the neck, a symptom which did not exist two hours previously. This swelling made Louis conclude, that the impurity of the operation was still greater. The friends whose confidence had been shaken by the objection he had expressed in relation about anatomy, were in the greatest embarrassment when they were told, that the child might die of an operation which he had represented as only a simple incision free from all danger. Louis was repeatedly asked, if he would be responsible for the child's life during the operation, and he was told, that if there were any thing to fear during the operation, it would be from the accident itself and not from the resistance required. This declaration was not perceived, and Louis withdrew, at the same time relating his opinion to the solution of two points of medicine, the effect of which would be useless and might be dangerous. The medicine was given in the night; the child was fringed with an operculum and quite unconscious. On Tuesday morning, Louis found her more quiet, smiling, who had said that she was getting better. Louis was wonderfully well. The operation, however, continued to be still attended with a rattling noise, which Louis had observed at the opening when the breathing was much more laborious. The child was nearly suffocated several times in the course of the day, and died in the evening, three days after the accident.

Bordenave, who had seen the patient, referred Louis to the child's death on Friday. The body was opened before a numerous assembly of persons. After making a longitudinal incision through the skin and fat along the trachea, between the sternohyoid muscles, Bordenave slit open the trachea, cutting three of its cartilages. At this instant every one could see the lesion, and Louis took it out with a small pair of forceps. It was smaller than the size with which this foreign body was suspected, that the operation would have had on the living subject the most salutary effect. The relations had to regret having sacrificed a child which was dearer to them than immolation and a remedy which the most judicious attempts could not remove.—(*Mém. de l'Acad. Royale de Chirurgie*, t. 12, p. 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, 113, 114, 115, 116, 117, 118, 119, 120, 121, 122, 123, 124, 125, 126, 127, 128, 129, 130, 131, 132, 133, 134, 135, 136, 137, 138, 139, 140, 141, 142, 143, 144, 145, 146, 147, 148, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, 162, 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183, 184, 185, 186, 187, 188, 189, 190, 191, 192, 193, 194, 195, 196, 197, 198, 199, 200, 201, 202, 203, 204, 205, 206, 207, 208, 209, 210, 211, 212, 213, 214, 215, 216, 217, 218, 219, 220, 221, 222, 223, 224, 225, 226, 227, 228, 229, 230, 231, 232, 233, 234, 235, 236, 237, 238, 239, 240, 241, 242, 243, 244, 245, 246, 247, 248, 249, 250, 251, 252, 253, 254, 255, 256, 257, 258, 259, 260, 261, 262, 263, 264, 265, 266, 267, 268, 269, 270, 271, 272, 273, 274, 275, 276, 277, 278, 279, 280, 281, 282, 283, 284, 285, 286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297, 298, 299, 300, 301, 302, 303, 304, 305, 306, 307, 308, 309, 310, 311, 312, 313, 314, 315, 316, 317, 318, 319, 320, 321, 322, 323, 324, 325, 326, 327, 328, 329, 330, 331, 332, 333, 334, 335, 336, 337, 338, 339, 340, 341, 342, 343, 344, 345, 346, 347, 348, 349, 350, 351, 352, 353, 354, 355, 356, 357, 358, 359, 360, 361, 362, 363, 364, 365, 366, 367, 368, 369, 370, 371, 372, 373, 374, 375, 376, 377, 378, 379, 380, 381, 382, 383, 384, 385, 386, 387, 388, 389, 390, 391, 392, 393, 394, 395, 396, 397, 398, 399, 400, 401, 402, 403, 404, 405, 406, 407, 408, 409, 410, 411, 412, 413, 414, 415, 416, 417, 418, 419, 420, 421, 422, 423, 424, 425, 426, 427, 428, 429, 430, 431, 432, 433, 434, 435, 436, 437, 438, 439, 440, 441, 442, 443, 444, 445, 446, 447, 448, 449, 450, 451, 452, 453, 454, 455, 456, 457, 458, 459, 460, 461, 462, 463, 464, 465, 466, 467, 468, 469, 470, 471, 472, 473, 474, 475, 476, 477, 478, 479, 480, 481, 482, 483, 484, 485, 486, 487, 488, 489, 490, 491, 492, 493, 494, 495, 496, 497, 498, 499, 500, 501, 502, 503, 504, 505, 506, 507, 508, 509, 510, 511, 512, 513, 514, 515, 516, 517, 518, 519, 520, 521, 522, 523, 524, 525, 526, 527, 528, 529, 530, 531, 532, 533, 534, 535, 536, 537, 538, 539, 540, 541, 542, 543, 544, 545, 546, 547, 548, 549, 550, 551, 552, 553, 554, 555, 556, 557, 558, 559, 560, 561, 562, 563, 564, 565, 566, 567, 568, 569, 570, 571, 572, 573, 574, 575, 576, 577, 578, 579, 580, 581, 582, 583, 584, 585, 586, 587, 588, 589, 590, 591, 592, 593, 594, 595, 596, 597, 598, 599, 600, 601, 602, 603, 604, 605, 606, 607, 608, 609, 610, 611, 612, 613, 614, 615, 616, 617, 618, 619, 620, 621, 622, 623, 624, 625, 626, 627, 628, 629, 630, 631, 632, 633, 634, 635, 636, 637, 638, 639, 640, 641, 642, 643, 644, 645, 646, 647, 648, 649, 650, 651, 652, 653, 654, 655, 656, 657, 658, 659, 660, 661, 662, 663, 664, 665, 666, 667, 668, 669, 670, 671, 672, 673, 674, 675, 676, 677, 678, 679, 680, 681, 682, 683, 684, 685, 686, 687, 688, 689, 690, 691, 692, 693, 694, 695, 696, 697, 698, 699, 700, 701, 702, 703, 704, 705, 706, 707, 708, 709, 710, 711, 712, 713, 714, 715, 716, 717, 718, 719, 720, 721, 722, 723, 724, 725, 726, 727, 728, 729, 730, 731, 732, 733, 734, 735, 736, 737, 738, 739, 740, 741, 742, 743, 744, 745, 746, 747, 748, 749, 750, 751, 752, 753, 754, 755, 756, 757, 758, 759, 760, 761, 762, 763, 764, 765, 766, 767, 768, 769, 770, 771, 772, 773, 774, 775, 776, 777, 778, 779, 780, 781, 782, 783, 784, 785, 786, 787, 788, 789, 790, 791, 792, 793, 794, 795, 796, 797, 798, 799, 800, 801, 802, 803, 804, 805, 806, 807, 808, 809, 810, 811, 812, 813, 814, 815, 816, 817, 818, 819, 820, 821, 822, 823, 824, 825, 826, 827, 828, 829, 830, 831, 832, 833, 834, 835, 836, 837, 838, 839, 840, 841, 842, 843, 844, 845, 846, 847, 848, 849, 850, 851, 852, 853, 854, 855, 856, 857, 858, 859, 860, 861, 862, 863, 864, 865, 866, 867, 868, 869, 870, 871, 872, 873, 874, 875, 876, 877, 878, 879, 880, 881, 882, 883, 884, 885, 886, 887, 888, 889, 890, 891, 892, 893, 894, 895, 896, 897, 898, 899, 900, 901, 902, 903, 904, 905, 906, 907, 908, 909, 910, 911, 912, 913, 914, 915, 916, 917, 918, 919, 920, 921, 922, 923, 924, 925, 926, 927, 928, 929, 930, 931, 932, 933, 934, 935, 936, 937, 938, 939, 940, 941, 942, 943, 944, 945, 946, 947, 948, 949, 950, 951, 952, 953, 954, 955, 956, 957, 958, 959, 960, 961, 962, 963, 964, 965, 966, 967, 968, 969, 970, 971, 972, 973, 974, 975, 976, 977, 978, 979, 980, 981, 982, 983, 984, 985, 986, 987, 988, 989, 990, 991, 992, 993, 994, 995, 996, 997, 998, 999, 1000.

This case strikingly illustrates the symptoms which result from the presence of foreign bodies in the trachea, and shows the only surgical proceeding which can be of use. But among the phenomena apparently difficult of explanation, is the cause which at intervals followed the afflicting cough.—*See Dr. Boerhaave's Case in Med. Obs. Voyes vol. 12, p. 61.* Answere, however, has dispelled much of the doubt of this matter. It is known, that the whole coat of the trachea is much less sensible than the mucous glands. A foreign body, then, a body, only remains a certain time in that coat without much inconvenience, the passage being only somewhat obstructed, according to the position of the substance. It may even remain several days, weeks, or years, without producing any symptoms of its presence, except a slight sensation of constriction, and this is what happens when the body lodges in one of the ventricles of the larynx. Cases of this kind are to be found in Truppius, Bartholin, and many other observers. But when the substance substance gets its position and is carried into the trachea, the irritation which it produces there, and particularly about the larynx, sometimes coughing; and it, in the first, the foreign body should become fixed between the apex of the glottis, it may cause inflammation, and, as probably has happened in many of the cases of suffocation from extraneous substances.

Another remarkable circumstance which deserves more attention, as it confirms the position of a foreign body in the trachea, is the emphysema which appeared about the clavicle towards the termination of the case. Louis did not believe that any of the persons who saw the patient could ascertain a just idea of the origin of this symptom. The supposition that the obstruction which the foreign body caused, for two days, to the free passage of the air, might have occasioned a forcible distention of the trachea, and a rupture of the membrane which connects together the cartilaginous rings of this tube, was dispelled by the examination after death. The windy tumour had not originated in the circumference of the trachea; here its limits were very wide. The very substance of the lungs and the mediastinum were emphysematous. The air confined by the foreign body had ruptured the air-vessels during the violent fits of coughing, and thus continued itself into the interlobular cellular substance of the lungs. Thence it had passed into the cellular substance of the lungs; and afterward into that containing the pleura, communicating with the outer surface of these organs; and by the communication of these cells with each other, it had produced a prodigious swelling of the cellular substance between the two layers of the mediastinum. The emphysema is so general, it length made its appearance above the clavicles. The swelling of the lungs and the surrounding parts, in consequence of the introduction of air into the cellular substance, is a manifest sign of suffocation. The inflammation appears to be so natural an effect of the presence of a foreign body in the trachea, that one can hardly believe it is not an essential symptom, though before Louis he neither had been noticed of it.

Foreign bodies in the trachea, however, do not always cause death so suddenly, which may be owing to their smallness, their position, or the situation in which they are fixed. An example is related in the *Epitomae Cur. Naturae*, lib. 2, cap. 13. As a woman was swallowing a cherry, the stone of the fruit passed up the trachea. A violent cough and excessive efforts, as it were, in vain, were the first symptoms of the accident, and of those the patient thought he should have died. A sleep of some hours followed the terrible

agitation, and the patient afterward did not feel the least inconvenience during a whole year. At the end of this time he was attacked by a cough attended with fever. These symptoms became worse and more every day. At length the patient examined a stone as large as a walnut. It was externally composed of tartarous matter, to which the cherry-stone had served as a nucleus. A copious purulent expectoration followed the discharge of the foreign body, and the patient died consumptive some time afterward. No morbidness is made of the body being opened, but from the symptoms, there is every reason to believe, that an abscess must have arisen in the substance of the lungs from the presence of the foreign body. That foreign bodies in the trachea, even when they do not induce pressing symptoms of suffocation, may ultimately kill the patient by inducing diseases of the lungs, is proved by several cases on record, and particularly by one which occurred in Bessault's cherry-stone was lodged in one of the branches of the trachea; the patient would not consent to an operation, and died in two years after taking laudanum.—(*See Quarterly Jour. de Medecine, t. 2, p. 235.*)

Some valuable observations, confirming the necessity of an early recourse to bronchotomy, in cases where foreign bodies are lodged in the trachea, have been published by Pelletan. In one case, in which a bean had fallen into a child's trachea, and in which the most urgent symptoms of suffocation had prevailed for four days, and convulsions during the last thirty-six hours of this space of time, Pelletan performed the operation, which a third year since, under whose management the patient was first placed, had neglected to do at an earlier period. Upon the trachea being made into the trachea, the bean was immediately thrown out within distance of two feet, and the child for a time was relieved. The little boy now is extremely weak, that it was at one time supposed he was dead. However, with some assistance, he gradually revived, and regained his senses, called his parents, and asked for such things as he wanted.

This incident made lasting impressions on the parents, after which, convulsions came on again, and the child died fourteen hours after his operation.

Notwithstanding the urgent appearance of all the blood-vessels of the brain, as described after death, the little boy had yet received a degree of relief at the instant of the foreign body being extruded. Pelletan deems it unnecessary to insist on the great possibility of success that would have attended the operation had it been performed at an earlier period.

Of such success, Pelletan gives us the following example.

In the month of May, 1768, a child about three years old was brought to the Hôtel-Dieu, who, in playing with some French beans, and putting them into its mouth, let one of them slip into the trachea. For three days the child was afflicted with a continued cough, and sometimes the symptoms of suffocation were most pressing. The time had been spent in administering opium, introducing instillations into the nostrils with the design of forcing the foreign body into the stomach, and in inhaling the vapours with a pernicious advantage, arising from the very long intervals of repose which the child experienced, during which, however, a cutting in the throat continued, a characteristic mark of the accident. Pelletan accordingly decided to perform the operation. The child was very fat, and this circumstance, together with the small diameter of the trachea at this age, rendered the exposure of the anterior portion of the larynx difficult. Pelletan was at this moment struck with the reflection, that bronchotomy should never be attempted except by men of science, coolness, and experience in operations. The rings of the trachea, however, were as large as cat, and there was no sensitive interval between the larynx and the expansion of the bronchial body. The lungs and pleurae considerably with the moisture. The child soon revived in life, a spike freely; it was only troubled with coughing, the effect of a small quantity of blood passing itself into the trachea, which had been instantly expelled again. This event has the appearance of convulsion, and may alarm those who do not understand it; but according to Pelletan, it is the guarantee of the patient's life, by expelling immediately and without difficulty, whatever happens to get into the trachea. The wound

was healed in twenty days, and the child's voice was not perceptibly altered.

In another interesting case recorded by the same writer, a pebble was lodged in the windpipe, and the case, not being understood, was treated for about three weeks as a simple inflammation of the lungs. At last, when a simple inflammation of the lungs, and by placing the child in a horizontal position the stone was seen disengaged through the trachea. The patient was immediately removed to the effects of the inflammation of the lungs, and injury which these organs had sustained, would never be cured, and the child died puffed out eight hours afterward.

Pelletan recalls other cases in which the foreign body, being fixed in the trachea, could not be forced out by the hands as was in the previous kind, but was, by means of a further operation, disengaged. In one instance Pelletan made a long cut in the windpipe of a child, but nothing could be accomplished. A probe, wrapped round with some moist linen, was then introduced several times up and down the trachea, without making a good deal of impression, and the child continued to breathe very well through the opening in the trachea. The foreign substance was presently brought to the surface and extracted; it proved to be part of the jaw of a small bird, with many sharp teeth in it. This child was afterwards a perfect recovery.

In another instance, a young man came to the Hôtel-Dieu, in consequence of having suffered for six weeks with a severe cough, frequently accompanied with a sense of suffocation. These complaints, on inquiry, were ascertained to arise from a foreign body having fallen into the trachea. An attempt was however made in this tube; but through the trachea could be felt, it could not be extracted with the finger. The tracheal cartilage was now divided, and the foreign body came out of the left ventricle of the lungs. The man recovered.

In one case related by Pelletan, a partial trachea of wood got down the pharynx, and gave rise to most dangerous symptoms. The foreign body was described as being so large that the symptoms could not but suppose that the complaints were owing to an inflammation of the lungs, as it seemed to be impossible of extruding the pharynx. The introduction of instruments down the pharynx, however, produced no effect; but, on dividing the thyroid cartilage, Pelletan passed his finger under the larynx, and, without knowing it, pushed the point of scissor towards the pharynx, when, with the aid of a probe, it was found in the pharynx and extruded. The patient experienced considerable relief, and got quite well.—(*Chirurgie Clin. t. 1.*)

With respect to bronchotomy or laryngotomy, in cases in which extraneous substances are supposed to be lodged in the trachea, one important caution seems necessary, viz. whenever the foreign body is above a certain size, a probing should be passed down the trachea before the incision is made, for very similar symptoms to those which proceed from extraneous substances in the trachea may be caused by the lodgment of foreign bodies in the windpipe. In 1841, bronchotomy has actually been performed, while the extraneous substance was in the trachea, from which last operation no attempt was made to disengage it, and the patient lost his life.—(*See Medical Clin. de Bessault, t. 2, p. 231.*) Examples in which various extraneous bodies have been successfully extruded by means of bronchotomy, are recorded by Bland.—(*See Schröder on Schenck, de Jurep. 120; Gynæc. Jurep. de Med. vol. 12, p. 44; Bland, Medico-chirurg. t. 1, p. 1035; Bland, Med. Transact. vol. 1, 1774. De Bland, in Med. Clin. Trans. vol. 1, 1774.*)

A bronchotomy has been proposed in cases in which the tongue is so enlarged as to fill up the passage through the larynx. In such a case, an attempt might be made to enlarge the larynx, in which a foreign body larger than in the natural state. Various and such the usual occurrence: "The enlargement of the windpipe is a frequent symptom, however, of a general inflammatory condition, of general oedema, and of a general tubercular condition, or of a general cancerous condition."—(*See 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100.*) They are also sometimes quite accidental, as, for instance, the cases which happen from the strangulation of the trachea, or the unskillful employment of intubation. In

B. Hall gives an example of the latter sort. He says, that the patient had taken in a very short time so large a quantity of mercury, that the part became extremely swollen, and the heart and, though all the usual remedies were tried, soon had the fatal effect. Bronchotomy was delayed till the patient was nearly suffocated; he then was intubated as soon as an opening was made in the trachea. Soon after objected to this practice, alleging that sufficing the trachea will bring relief in time.—(Hall's *op. de Aëriæ et puræ Chæmæ, art. Bronchotomie*.) Hall's observations on the swelling of the tongue, and the most efficient means of relieving it, serve to confirm the latter assertion.—(Herr. de Chæm. & Chirurgie, p. 14, p. 468, &c. 1661, in 12mo.)

In cases of the preceding description, Desault would have advised the introduction of a elastic gum catheter over the root into the trachea, in order to enable the patient to breathe, until the swelling of the tongue had subsided.—(See *Chirurgie Chir. de Desault*, t. 2, p. 216.)

1. Bronchotomy has been recommended when both the lungs are in danger, as very dangerous to respiration. Here the inflammatory swelling is contained; this extremely soon subsides, and the spontaneous healing of the wound, at the opening of a small pneumothorax, generally restores all necessary for an entire recovery. But even in acute inflammation and great enlargement of the pulmonary vessels, the patient with symptoms danger of suffocation, the practice has been sometimes deemed necessary, as the cases cited from Flajus in the preceding section are sufficient to prove. The disease, however, which I here wish particularly to specify, at sometimes rendering bronchotomy indispensable, is a chronic enlargement of the lungs, the case mentioned in the same Thesis. From the remarks on the disease, however, it will be seen that there is to be expected from the extension of the disease, that from the operation there is question. Besides, before this disease is so large as to threaten suffocation, they should be out every performance performing bronchotomy, which might relieve the suffering, but could not remove the cause of the difficulty of breathing. In general, there is no urgent danger of suffocation of the swelling in such cases, only to cut up the posterior aperture of the mouth, but also the posterior openings of the nostrils, which is exceedingly rare. Besides, of obstructed respiration does enlargement of the lungs, Desault preferred the introduction of the elastic catheter from the nose into the cavity, the operation of bronchotomy. It is not common for a polypus to make this operation necessary. However, however, mentions a case, in which the patient was suffocated as the surgeon was going to cut up a tumor of this kind; no doubt this patient might have been cured if bronchotomy had been previously performed. Polypus growing in the larynx itself are very rare, but catalogues are recorded, and if such measure happen to obstruct the glottis, the patient is instantly suffocated. Some instances of this kind are related by Haller. The only mode of getting at such swellings, so as to cut them free, is by performing bronchotomy.—(See *Chirurgie Chir. de Desault*, t. 2, p. 251, 255.)

2. Lastly, bronchotomy has been recommended to be done in persons recently suffocated by drowned. Bitharding is the first author who has treated of the necessity of this operation in the latter case, in a letter addressed to Schroeder, entitled *De Methodo submersorum revivendi per Laryngotomiam*. Haller approves of the practice, provided the trachea section, with which the lungs are loaded should rupture to be discovered in this manner. Bitharding supposes that drowned persons have no water in their chests or cavities of the lungs, and that they perish suffocated by want of air and respiration, and that while the person is under water the vegetable applies itself as closely over the glottis, that not one drop of water can pass. But these assertions are quite contrary to the evidence of experiments made by Lomax, who drowned animals in colored fluids, and proved that such air as is dissolved in the water, with which the air-vessels and cells are filled. Lomax also proved even when he had perished under water, but in these he never found the vegetable applied to the glottis in the manner described by Bitharding; indeed, many prove the impossibility of its being so. Bitharding's doubts were

wrong, and he did not use any power to distend the lungs with air, the mere position of bronchotomy might have been useful. When there is a free communication between the cavity of the lungs and the atmosphere, the air will not expand those organs. If the respiratory muscles are no longer act. Hence, after opening the trachea, and letting a man's water run out of his mouth to prevent, the pipe of a pair of bellows should be introduced, and the air blown into the lungs.

Desault was right in his opinion, that drowning is a species of suffocation, and that the process of respiration is the cause of death. Hence the propriety of introducing air into the lungs as speedily as possible, whenever asphyxiation has not been so long continued that every hope of respiration is over. Indeed, it is proper to distend the lungs with air in all cases in which asphyxiation has been recently suspended by suffocation, immersion, either water, or by noxious vapours and gases. This measure is highly proper, in conjunction with electricity or galvanism; the communication of warmth to the body; the application of strong stimulants to the nostrils; rubbing the body with warm flannels; and the injection of warm wine or brandy and water into the stomach through a hollow syringe. However, indeed, Lomax, which have had the sanction of the Royal Humane Society, should be repeated, as the operation of this part are peculiarly destructive of the vital principle, and not easily stimulating. Last night to find one last person contained by me respectable a surgeon as James Barry, who joins the rest of the French surgeons in condemning electricity and bronchotomy. He speaks in favour of opening the jugular vein, exposing the body to the air, incision, &c. On dissecting the bodies of some drowned persons, Barry found, as Lomax had described, that the membranes of the lungs were filled with water instead of air, and that the epiglottis was raised and applied to the glottis.—(See *Mémoires de Chir. Histoire*, t. 1, p. 82—85.)

There are many modern practitioners who consider bronchotomy needless in cases of suspended respiration, because it is considered, that, as the patient is always destitute of sensation, it is too easy to be pushed into the trachea from the nose or mouth, for the purpose of inflating the lungs. Either the curved pipe of a pair of bellows may be introduced into the glottis through the mouth, or an elastic gum catheter may be pushed into the trachea from the nose. "On peut mettre en usage d'intubation Corps Politain" after its application, on les défauts suivants: *1.°* que le patient ne peut pas respirer, donc est difficile car son état est si grand d'inflammation, mais même l'air ne peut pas pénétrer, et la cause est commandée pour souffler de l'air dans les poumons, en même temps qu'il peut causer une terminaison fatale." *2.°* Bitharding, non calidè confidet, si a trachea per streptum submersorum, et non modo de oris, sed per aperturam in ore non respirare potest, sed in respiratione non est liberatus."—(Chirurgie Chir. t. 1, p. 251.) Desault likewise conceived, that the lungs might be easily inflated without performing bronchotomy.—(Chirurgie Chir. t. 2, p. 255.) Mr. A. Burns adopts the same sentiment.—(Surgical Anatomy of the Head and Neck, p. 308.) My own individual opinion upon this subject is, that if a surgeon knows that he can inflate the lungs as completely and expeditiously without performing bronchotomy, as he can by making an incision in the trachea, he is right in dispensing with the latter operation. But in the possibility of cases of suspended respiration (that of new-born infants, excepted, where bronchotomy would be an objectionable modernism), I wish to state whether in actual practice bronchotomy will not be found the best and most speedy means of sending the lungs to distend the lungs with air. If you follow Desault's suggestion, I confess that you are likely to be some minutes longer in getting the elastic catheter from the right nostril into the larynx, than you would be in getting into the trachea and introducing into the incision the handle of a pair of bellows. Disposing the elastic catheter introduced, will you now be able to distend the lungs with air in an adequate degree, as object of the highest moment? A pair of bellows seems to me almost essential to this purpose. I shall say nothing on the probability of many practitioners following the present approved with the vegetable still of water.

If a pair of bellows with a curved pipe be employed, many surgeons would be a considerable time in getting

the needle into the glottis, and, in the mean while, every spark of life might be extinguished. On the other hand, bronchotomy (performed by a vein of artery cut and skin) is an operation free from danger. It may be executed with a penknife if no better instrument be at hand; and when the incision has been made, a pair of common forceps will suffice for the dilation of the lungs. But I conceive that bronchotomy were a perfect operation; that the lungs could be effectively distended without the employment of bellows; that the wound could generally be accomplished so expeditiously without cutting into the trachea; I should be so early to join in the commendation of this last proceeding as any contemporary writer. Greatly, however, as I respect most of the authors who differ from me on this point, the reasons I have assigned persuade me from subscribing to their sentiment. Doctors who may be regarded as the founders of the doctrine, ascribe the utility of bronchotomy, it is said, to be observed, speak only from theory, and not actual practice, in these cases.

With respect to the performance of the operation, no preparation is necessary, as delay only increases the danger. The patient being seated in an arm-chair, or, what is better, laid on a bed, with his head hanging backwards, an incision is to be made, which is to begin below the cricoid cartilage, and to be continued downwards about two inches, along the space between the sterno-chondral muscles. Care should be taken not to cut the lobes of the thyroid gland, but a troublesome and dangerous bleeding be occasioned; and, as the left subclavian vein lies a little below the upper part of the first bone of the sternum, the incision should never extend so low as this point. The knife must not be carried either to the right or left, in order to avoid all risk of injuring the large blood-vessels situated at the sides of the trachea. The incision in the integuments having been made, the sterno-chondral muscles are to be pushed a little towards the sides of the neck, so as to bring the trachea fairly into view. Many authors recommend the point of the knife to be then introduced between the third and fourth cartilage of the trachea, and the opening to be enlarged transversely. It is true that in this way an opening may be safely made, large enough to admit a small cannula to be introduced. It is safer, however, in all cases, to enlarge the opening in the perpendicular direction, by raising them within outwards. There is an advantage in avoiding a wound of the cartilages of the trachea, the only reason assigned for cutting the membranes between them, is a transverse diameter; while a sufficiently large opening remains that be safely obtained, in cases in which it is necessary to introduce the muzzle of a pair of bellows, in order to inflate the lungs. In short, it is safer and better in every instance, to make the wound in the trachea in a perpendicular manner.

I have stated that bronchotomy may be performed by a man of ordinary skill without danger. It is far otherwise with a careless practitioner. We read in Denon's work, that in one instance the carotid artery was wounded. The following case, given by Mr. J. Harris, seems entitled to notice. "The patient's symptoms are in risk in some subjects. There were in this case a high on the forepart of the trachea, so as to reach the lower border of the thyroid gland. Even the right carotid artery is not always safe. I am in possession of a case, taken from a boy of twelve years of age, which shows the right carotid artery crossing the trachea in an oblique direction. In this subject, that vessel did not reach the lateral part of the trachea till it had ascended four inches and a quarter above the top of the sternum.

When both carotid arteries originate from the anterior trachea, there is considerable danger in performing the operation of bronchotomy; for in such cases, the left artery crosses the trachea pretty high in the neck. Professor Denon has seen a specimen of this disposition in a male subject, and I have met with two.

These varieties in the course of the arteries are worthy of being known and remembered; they will teach the operator to be on his guard, since he can never, a priori, ascertain the arrangement of the vessels with any degree of certainty. It will improve to his mind the impropriety of using the knife rather than merely to divide the integuments and bones. If

he then clear the trachea with the fingers, he will never injure any of the large vessels. When with the finger he has fairly brought the trachea into view, he can be excessive carefully, whether any of the large arteries be in front of it; and if he find one, he ought to depress it towards the chest, before he penetrates into the windpipe.

In writing, and the press, the preferable plan is to cut the muscles from below upwards, avoiding injury of the thyroid gland."—(See A. Burns on the Surgical Anatomy of the Head and Neck, p. 204, 205.)

As Mr. Francis Wilson, of Dublin, was performing tracheotomy in a case of croup, he observed, "on separating the edges of the sterno-thyroid muscles, the two thyroid veins were exposed, together with a considerable arterial branch, the junction of which was quite perceptible, directing its course upwards towards the crux of the thyroid gland." Mr. Wilson states, that the artery here spoken of was the branch which Mr. Harrison, in his work on the Surgical Anatomy of the Arteries, describes under the appropriate name of middle thyroid artery; and though looked upon as an irregular distribution, it is sufficiently frequent to make it necessary for the surgeon to be upon his guard.—(See Dublin Hospital Reports, vol. 4, p. 262.)

When bronchotomy is performed for the purpose of inflating the lungs, the cut in the windpipe must be made somewhat larger than when an opening is required merely to enable the patient to breathe through a small cannula. The larger size of the pipe if the bellows is the reason of this circumstance.

When a cannula is introduced, care must be taken not to push it too far into the wound, lest it open its opposite side of the trachea. This is a caution to which Fabricius ab Aquapendente dwells very strongly, and with good reason.

When tracheotomy has been performed in a case where respiration is secreted in such abundance, that the patient is threatened with suffocation from its accumulation, and his inability to cough it up, owing to the wound in the windpipe, Dr. Cullen is an advocate for the use of a large cannula for the sake of permitting free expansion, the only substitute for trachea, which the patient can no longer effect.—(See Edin. Med. Journ. N° 94, p. 92.)

Small as the vessels may be which are divided in bronchotomy, they necessarily bleed so much as to create apprehension, and even prevent the continuance of the operation. There is a case in Van Meulen's Commentaries confirming this remark. A Spanish soldier, aged twenty-three, was in the most urgent danger from an inflammation of his throat. It was thought nothing could save him except tracheotomy. After the longitudinal cut in the skin, and the separation of the muscles, the trachea was opened between two of the cartilages; but the blood issued still into the wound, and excited so violent a cough, that the cannula could not be kept in by any means, though it was replaced several times. Less remarks that in this instance the patient's head should have been tilted downwards, in order to keep the blood then flowing backwards into the trachea. It is asserted, that the opening of the vein was not always opposite the incised wound, in consequence of the contraction of the muscles, and that the patient in this accident could hardly breathe. Hence, Vigli is induced to slit open the trachea, down to the sixth cartilage, and, as it was only then that he inclined the patient's head forwards. The bleeding now ceased, the patient sufficed with ease, and on the second day the inflammation was so much better, that respiration went on without the aid of the opening in the trachea.

The most simple and natural mode of obviating all trouble from the extrusion of blood less the trachea, is to use any bleeding branch of the thyroid artery or vein before the windpipe is opened.

Sometimes the cannula becomes obstructed with clots of blood. Such an accident nearly visited a patient at Edinburgh. An experienced person happening to be at hand, suggested the introduction of a second cannula into the first; the second one being taken out and washed as often as necessary, and then replaced.

The use of the cannula must be continued as long as the causes obstructing respiration remain. Thus, in the very interesting case of croup, detained in a

inflammation. When the burnt surface is very large, the effects of the inflammation are not confined to the part which was first irritated, but even extend a great deal of time; and in certain cases, a common state, which may lead to death.

It has been observed, that persons who die of severe burns seem to experience a remarkable difficulty of breathing and expansion of the lungs. These organs and the skin, are both concerned in expanding a large quantity of water from the circulation, and their participation in this function may perhaps afford a reason for the respiration being often much affected, when a large surface of skin is burnt. However, the kidneys perform the same office, and they are not particularly affected in these patients; so that the asthenic symptoms frequently noticed in cases of burns, are probably owing to a sympathy between the lungs and skin, or to a cramp of the former instrument.

According to Desgenettes, erysipelas will always always trace an inflammation of the vessels, the entrance of the inflammatory canal; a circumstance used to explain these various instances of death, which, on admission, were the effect of the point of healing. — (See *De Erysipelo* per Salomon, *tab. de MM. Simon et Biondi*.)

Two general methods of treating burns have at all times been employed. One consists in the application of substances which produce a cooling, or refrigerant effect; the other is the employment of caloric, or stimulating substances. Dr. Thomson is satisfied, that each of these different modes may have its advantages in particular cases. — (See *on Inflammation*, p. 386.)

The practice mostly resorted to in this country, some years since, was explained by Mr. R. Bell. When the skin is not destroyed, but seems to suffer merely from irritation, relief may be obtained by dipping the part affected in very cold water, and keeping it in this state incessantly. This author states, that patients who received part of the body being water would also patients even; as sometimes, however, much to be added, and a practice not likely to be followed. In some cases, sometimes afford immediate relief; but in general, as frequent applications are best. Strong linseed oil or alcohol is particularly praised. At first the pain is increased by this remedy, but an agreeable soothing sensation soon follows. The parts should be immersed in the water, and when this cannot be done, wet old linen soaked in the application should be kept constantly on the burn. The liquor plantagi, expressed dilute is recommended. It is said to prove useful, however, only by being continued, as equal benefit may be derived from a strong solution of wheat. For such applications were frequently made with the view of preventing the formation of vesicles; but Mr. R. Bell always remarked, that these were less pain when the blisters had already appeared, than when prevented from doing, by remedies applied immediately after the occurrence of the injury.

The application should be continued as long as the pain remains; and as extensive burns creating great irritation, require should be remembered. The degree to which patients are situated are often attended, however, more relief from giving them any thing else.

Some successful opening the vesicles immediately, others assert, that they should not be opened with. Mr. R. Bell thinks that they should not be opened till the pain arising from the burn is entirely gone. At this period, he says, they should always be prevented; for when the vesicles are allowed to last long upon the skin, it has a bad effect, and even renders some degree of prostration. Small punctures, not large vesicles, should be avoided. All the fluid having been discharged, a mixture of wine and oil, with a great proportion of the extract of opium, or laid, is to be applied.

On the subject of opening the vesicles in burns, Dr. Thomson observes, that the diversity of opinion arises from the different effects resulting from the particular manner in which the opening is made. "If a portion of the vesicle be removed so as to permit the air to come into contact with the injured surface of the skin, pain and a considerable degree of general irritation will necessarily be induced; but if the vesicles be opened externally with the point of a needle, so as to allow the serum to drain off slowly, without at the same time allowing the air to enter between the vesicle

and cover, the early opening of the vesications will not only not increase pain, but will give considerable relief, by dissolving the state of tension with which the vesications are almost always, at a greater or less degree, accompanied. When opened in this manner, the vesications often fill again with serum; but the patients may be repeated as often as is necessary, without any hazard of aggravating the inflammation. Great care should be taken in every instance, to preserve the raised portion of callosity as entire as possible." — (See *Lectures on Inflammation*, p. 386.)

When there is much irritation and fever, blood-letting, and such remedies as the particular symptoms demand, must be advised. The degree of the pain being frequently small, quick, and violent, bleeding is at present not often employed. As Dr. Thomson remarks, however, it may become necessary in patients of a strong robust constitution, in whom the symptoms seem to assume an inflammatory type. He has observed a single bleeding prove great relief in these cases; and he does not remember a case where bleeding was followed by trifling effects. — (P. 386.) When the skin sloughs, the treatment does not differ from what will be described, in speaking of Ulcers.

When burns are produced by steam, and the skin more or less destroyed, cooling emollient applications were formerly thought most effectual, and a liniment composed of equal proportions of lime-water and lavender oil, was the greatest celebrity. Even at this day, the application is very often employed. Mr. R. Bell advises it to be put on the parts by means of a wet lint, and as the application and removal of the lint dressing, are often productive of much pain. The same author admits, however, that there are some cases in which Goulard's cerate, and a weak solution of the tincture of lead, more quickly procure ease than the above liniment.

The vesicles having come away, the sores are to be dressed according to various principles. — (See *Ulcers*.)

When sores are produced by gas powder, some of the grains may be fitted into the skin; these should be pushed out with the point of a needle, and an emollient poultice applied, which will dissolve and bring away any particles of gas powder yet remaining.

Rare parts which are tender, frequently grow together in the progress of the cure. The fingers, toes, sides of the nostrils, and the eyelids, are particularly liable to this occurrence; which is to be prevented by keeping dressings always interposed between the parts liable to become adherent, until they are perfectly healed.

The sores resulting from burns are perhaps more disposed than any other ulcers to form large granulations, which rise considerably above the level of the surrounding skin. No position should now be used. The sores should be dressed with any moderately stimulating, astringent ointment: the vesicles callosities with the suppurative tissue with the point, but dry, nitric acid is now generally preferred; and if the part will stand the application of a caustic, the pressure of it will be of immense service in keeping down the granulations, and rendering them more healthy. When these methods fail, the sores should be gently rubbed with the digestion stramonium.

As the dry and hot state of the skin Dr. Thomson is an advocate for the diaphoretic. "Tincture of opium" says he is also necessary; but it is in general best to employ only the purging sort, or amount of the trouble and pain which having always given the patient. Antispasmodics are often required, not only to procure sleep, but even a temporary alleviation of the pressure of the pain which the burn occasions. A mild vegetable and narcotic diet must be used during the period of the symptomatic fever. Animal food, wine, and other condiments may be required in the progress of a suppurating burn; but they are not necessary at first, and when given in this stage, are almost always injurious. — (See *Lectures on Inflammation*, p. 386.)

With respect to the general applications recommended by the foregoing, he generally prefers, in cases of superficial burns, cooling and refrigerant remedies. When there are vesicles, and suppurating takes place without ulceration, he advises us, after suppuration have ceased to produce beneficial effects, to use the linimentum opium rectum. However, where the progress of suppuration is slow, he recommends, instead

of this treatment, containing lead or tin, particularly the opiate and opium.

In the alarming state of suppurating lesions, to perform excellent cathartics. But when the discharge continues, or becomes more profuse under the use of poultices, they are to be left off, and antiseptic poultices employed, such as lime-water, the evaporated decoction of oak-bark, a weak solution of sulphate of copper, &c.

When the parts are desloughed and converted into sloughs, Dr. Thomson does not think it necessary usually whether vinegar, dry hyssopus, thymopaste, spirits of wine, or essential poultices be at first employed. He acknowledges, however, that the poultice is the remedy under the application of which the separation of the dead parts is most easily and agreeably accomplished.

"The opium (says he) at present most deserving the attention of medical practitioners with regard to the use of the water-poultice position is better in whatever we should apply it immediately after the burn has been removed, or at least for some hours, as has been so strongly recommended, dressing with vinegar, spirits of wine, or oil of turpentine. My own experience has not been sufficient to enable me to determine this point to my entire satisfaction. Yet I think it right to state to you, that in a number of fatal cases at different times, I have had occasion to see burns to which contrary excellent poultices had been from the first applied, sloughs and gangrenae faster, and in a more kindly manner, than similar burns in the same persons, in which it was removed the Carrot Oil (lin. calc.) and in others again oil of turpentine, were applied at the same time with the poultice."—*See Lectures on Inflammation*, p. 609.

MR. CLITHERON'S PLAN.

This gentleman, who was a brewer at Edinburgh, was induced to pay great attention to the effects of various modes of treating burns, on account of the frequency of these accidents among the oven-workers. His observations led him to prefer the immediate application of vinegar, which was to be continued for some hours, by any of the most convenient means, until the pain abated; and when this returned, the vinegar was repeated. If the burn had become severe so as to have produced a separation of parts, these, as soon as the pain had ceased, were covered with a poultice, the application of which was continued about six or at most eight hours; and after its removal, the parts were minutely washed with very dilute powdered chalk, so as to take away every appearance of moisture on the surface of the sore. This being done, the whole burnt surface was again covered with the poultice. The same mode was pursued every night and morning until the cure was complete. In the use of poultices, he refused the wines too much, a glass or two of wine, containing the extract of bark, was applied; but the chalk was still continued upon the part.

With respect to general treatment, Mr. Clitheron allowed his patients to eat, boiled or roasted food, or in short any plainly dressed meats which they liked. He did not object to their taking moderate quantities of wine, spirits and water, tea, or porter. He never had occasion to order bark, or any internal medicines whatever, and he only saw it right to administer it in blood. When the patient was asleep, Mr. Clitheron ordered boiled potatoes and pears, or some other laxative nourishing food, and sometimes an opiate, but never any purgative, as he remarked that the disturbance of regularly going to sleep was distressing as a patient with bad sores. Besides, he thought that a habitual weakness and laxness were always a sure or least brought on by purgatives. From the effects which he felt these have upon himself, and observed them to have upon others, they did not seem to have a powerful tendency to remove heat and break suppuration as is generally supposed, and he believed that they more frequently carried off useful humours than hurtful ones.

Dietary medicine and was not found to answer as well as vinegar, and the latter produced most benefit when it was fresh and freely used.

He would neither Mr. Clitheron's treatment warmed the vinegar a little, placed the patients near the fire, gave them soothing warm infusions; and thus, there is every reason to think considerable success. His plan is so simple, and so easy to put into the execution of country and children, which is two advantages, after employing cold vinegar, with pain in an extensive degree.

The account of Mr. Clitheron's plan was published by Mr. Fraser—*See Med. Facts and Observations*, vol. VI.

MR. JAMES EARLE'S PLAN.

This gentleman was an advocate for the use of cold water exclusively; and published several copies of extensive tracts, in which this method was employed with the best effect. Cold water was recommended by Mr. Earle among the applications to burns, and it was not necessarily used long before Mr. James Earle communicated the result of his experience to the public.

"The method indeed is very simple. 'Cold is a remedy says Dr. J. Thomson, which has long been employed to diminish the inflammation of superficial burns. Rhazes directs, that in recent burns, cloths dipped in cold water, or of raw-silk soaked with wine, be applied as soon as possible to the parts which have been injured, and that these cloths be renewed frequently; and Avicenna says that this practice often prevents the formation of blisters.'—*Lectures on Inflammation*, p. 609.) Sir James Earle's plan, however, had the good effect of drawing attention to this method in the subject, and of leading surgeons to try the method in a great number of instances in which other more painful modes of treatment might otherwise have been employed. 'The burnt parts may either be plunged in cold water, or they may be covered with linen dipped in the same, and renewed as often as it appears warm on the part. The application should be continued as long as the heat and pain remain, which they will often do for a great many hours.'—*See Essay on the means of lessening the Effects of Fire on the human body*, New York, 1825.)

Some critics, however, in the application of cold water remedy when a scald just very large and extended upon the trunk of the body. It causes lesions, superficial as they may be, the patient is liable to be affected with cold shiverings; and these shiverings may be greatly aggravated by exposure and by the application of cold. Perhaps, therefore, in these cases warm applications might be preferred.—(*See J. Thomson's Lectures on Inflammation*, p. 203.)

MRS. LARRY'S PLAN.

It seems to me, that as the subject of burns there is, even at the present day, as much confusion of mind as in any part of surgery whatever. After all the progress which in two years has been made of surgery, cold applications, oil of turpentine, &c. a French surgeon, whose talents and experience as a practitioner entitle his opinion to the highest esteem, has recently emitted the expression of all such remedies. Larry, though a military surgeon, had had occasion to see numerous burns in consequence of inflammation. He declares that he has never been struck with the bad effects of suppurations, such as fresh water with the mixture of ammonia, myrror, the hyposphosphate ammonia, and the addition of opium to the water. He recommends dressing all dry burns with fine old linen spread with saffron extract, which, he says, has the quality of diminishing the pain and preventing irritation, by keeping the various parts from coming in contact with the air, or being pressed by the linen and clothes. This treatment is to be continued till suppuration takes place, after which Larry employs the extract of myrror for promoting the desiccation of the surface, and checking the extension of the sloughs. As soon as the dead parts have separated, he washes the wound with the saffron extract, for which he probably substitutes dry lint, with vinegar of lead spread with cerate. When the vessels around the limit of the edge of the sore, he keeps them bathed in the hyposphosphate, and he occasionally applies a weak solution of the oxyhydrate of mercury, or of the sulphate of copper.

Larry prescribes excellent and judiciously chosen remedies, which are to be taken warm, such as pulque of almonds, nutmeg, wine, and properly extracted hyssopus, rose-syrup, &c. His patients are never deprived of light nourishment, such as toast, gruel, eggs, milk, &c. He has found this system to answer, which he calls wetting and gently heating, almost always successful.—(*See Memo. de Chir. Militaire*, t. 1, p. 10.)

MR. LARRY'S PLAN.

From what has been stated, it appears, that in cases of burns, cold and hot, irritating and soothing, anodyne and emollient applications have all been employed

employed without such discrimination." But this is second treatment and always has been, and the law of the land and common usage is giving "hand-in-glove" treatment to all, in short, the whole of our population. It is true that Mr. Cushman, who chairs the panel, and several students already at Dr. Kowalski's law have stated the only reason for the lower status.

The former theory advanced by Dr. Gerlach, from whom it is believed, that as active and passive attributes both increased in action, there are two independent *depressiones* which act to arrest the activity of *passiva*: viz. the continuous or active of the part in first place, and finally dissimilating; secondly, the action of the system is to be increased to meet the increased action of the part, making the late as the reason in view: That any part of the system, during its action, increased to a very high degree, must conform to its growth, through its *active depresso*, either by the stimulus which caused the increased action, or some other having the power similarly to it, to be able to depress the extraordinary action, and thereby make the healthy action of the part.

With this view, looking the part to the five senses, to Dr. Keenick, the best mode of relieving any parts of the body are injured to which they cannot be done, the most successful applications must be used. For in this class there is little left of any of them being greater than that which originally caused the accident. The strongest rectified spirits, made still stronger by essential oils, are proper, and may also be used as much as the worst parts can bear. Vine and many other applications of the same kind, says Dr. Keenick, will give the most speedy relief. There are to be considered only for a certain time, for they cause the very ill which they are given to cure. They are then to be succeeded by less stimulant applications, until the parts are by *some* natural cures.

The information of *point* is to generate sub-points which must specify what the system is even doing, such as *alter, select, spiral, system, mine, wire*. And, to which there is the notion of continuity of action is allowed to last the shortest time possible, and the many of action is reduced, which constitutes the core.

Suppose, nevertheless, as a local spectator, we at first apply the standard alone, limited to the degree which the second part would bear witness against it; should afterward be gradually diluted with a lessened proof, and the first should be diminished, although gradually, as such a average provision, bringing us this tendency to deliver which should ever be continually guarded against, as being a most fearful system, and the incarnation of a violent sympathetic contagion; thus, the original that should be kept at a high temperature, and the action of the whole system aimed to as great a degree as may be safe. By this means the action of the whole is made to meet the increased action of the part, by which the lessening of the increased action of the part is put the action of the whole is pondered more easy. Thus more is said by Kantian, a unity of interest by both the external and internal means, leading to the satisfaction of the unity of action, and the case is understood.

It may be set, these circumstances can only take place when there is an internal action; and when the particles destroyed, other atoms should be freed, and so on. In reply to this remark, Dr. Keating distinguishes matter into two kinds; one in which the action of the part is only internal; and another, in which some parts have external action, while others are destroyed. It is of this consequence, says Dr. Keating, what is applied to the third part, as the destruction of one member depends upon the action of the other which causes it, and not upon what is applied to those which are lost. However, he never has an instance of a body in which, though some parts were totally destroyed, there were not always other parts in which there was only internal action. Now as the action is always to save living parts, and needs of are in the first instance will always be the same; viz., to cure the parts which have only an internal action, the first kind of which the first parts will not be the same, as their separation is a process of the system, each requires time, and, if the delay is to any extent, may rank the part affected, the system, and even, says Dr. Keating, calls up the energy of the powers to meet them. This must always be supported by every kind of effort of the body, and so on.

substitute the subject field in the context; but if the
 longer name has not, the power is given off the dead,
 not dead will substitute the living to themselves, and
 a resurrection exists.

When the living parts have been processed (usually by Dr. Serravallo), which, according to this treatment, will be in the course of two or three days, the dead parts will be more quickly absorbed, and the benefits of the process as they pass off will be increasing. The process must be assisted by keeping the surface of the system by diaphoretic medicines and a purgative diet. The supposition of the recovery will be greatly promoted by the application of the thymus of four to seven of cataplasms frequently renewed. These may be made of milk and honey, and some enveloped in oil or any material at hand, applied upon the surface. Such means need only be continued until the suppuration is completed.

After his death had occurred the system is reparation, he then found that gradually detaching from his essential plan diminished the secretion of pus, and nonfertility quickened the healing process.

When some parts are destroyed, there must be others with increased action; and in this case, according to Dr. Keenish, the foregoing mode will be the best for removing the living parts, and promoting the separation of the dead ones. Suppuration having taken place, the seeping of the system by any thing stimulant, either by food or medicine, should be carefully avoided. Should the secretion of pus continue too great, gentle stimulants and a spare diet are indicated. If any part, as the eye for instance, remains weak, with a tendency to inflammation, frequent bleedings, or small quantities of blood taken from the arms, are useful. For the purpose of debarking the poor skin, transplanted oil, or cod-liver oil and lime-water is equal parts, are good applications. Wounds of this kind heal very fast, when the circulation of pus is prevented by attention to diet; if the patient's strength permits support, small doses of bark taken two or three times a day is some- what well answer that purpose, without considering the attention to wine, ale, or spirits are apt to do. By attention to these particulars (testimony Dr. Keenish), I can truly assert that I have cured very many extensive and dangerous burns and scalds in one, two, three, and four weeks, which in the former method would have taken six or seven months; and since which I believe to have been incapable for the former period.

After explaining his principles, Dr. Korshak takes note of the various substances which have commonly been employed. Of these he would chiefly rely on alcohol, liquid ammonia, ethylaluminum chloride (as applied as a spray in the cooling process of evaporation), and spray of benzene.

In applying them, we are directed to proceed as follows: The injured parts are to be bathed, two, or three times over, with spirits of wine, spirits of wine with tincture, or spirit of turpentine, heated by standing in hot water. After that treatment, a poultice of the compound tincture infused with spirit of turpentine, is to be spread on dry cloth, and applied. This treatment is to be continued only once in twenty-four hours, and, at the second dressing, the parts are to be washed with pure oil, or liniment, made warm. When the scum on the tumor goes, tender applications must be made, if the cure is effected.

The yellow ointment stops the pores of the cloth (prevents evaporation), and thus confines the effect of the iodine to the target surface. The first dressings are removed on fear-and-civility fears. Dr. Kautskithinks of importance, that the exposed surface should be left uncovered as little as possible. It is therefore recommended to let the patients to urinate nude, before the dressings are removed, and then only to take off one piece at a time.

[illegible]

and in the furrows between alveoli and living parts, be introduced powdered chalk. Then a plaster is applied, and, in tedious cases, a poultice over the plaster.

With respect to the internal treatment, the author observes, that great advantage of the system arises in certain persons from causes which in others produce no effect, and that this depends on a difference in the degree of strength. Hence, he considers that as strength restores the assimilative capacities of parts, and weakness induces them, we should, in all cases, apply the system as strongly as we can, immediately upon the receipt of the injury. In considerable burns, he supposes a disappearance of action to take place between the injured parts and the system at large, or what he terms a section of the continuity of action; and that, by a law of the system, a considerable excretion arises, for the purpose of restoring the equilibrium, or restoring the constitution to that of the state of the part. Hence, Dr. Keenish is of opinion, that the indication is to remove the unity of action of the whole system, as much as possible, by evacuating it from a state as to remove the diseased action, and then gradually bring down the whole to the natural standard of action by slowly traversing the cooling process. Elixirs and tinctures, or other stimulants, are to be judiciously given in proportion to the degree of injury; and repeated once or twice within the first twenty hours, and afterward with care to be reduced, till suppuration takes place, when it will be no longer necessary to excite the system.

In a second essay, Dr. Keenish remarks, that, in the first species of burns, in which the action of the part is very increased, he has not found any thing better for the first application than the burned cream of tartar and cerium resin, thinned with water. In superficial burns, when the pain has ceased, he considers it advisable to derive from this application an about four and twenty blisters, and next the second dressing a digestive, antiseptic thinned with camellia oil, hyssopus, or the third day, with camellia oil, balsamum. This author has immediately seen secondary suppuration excited by the remedy. The most certain remedy for this unpleasant symptom is a digestive ointment thinned with oil, or a poultice of comfrey, and over this a large warm poultice. The ointment will finish the cure. Blistered parts be much susceptible of the system, as antidotes, prepared to the age of the patient should be given.

The growth of fungus, and the profuse discharge of matter, are to be removed, as already mentioned, by spreading powdered chalk to the surface, and by the use of purgatives, in the latter stages. The chalk must be very finely triturated.

Dr. Keenish's theories are, as far as I can judge, satisfactory: they may excite the fancy, but can never improve the judgment. They are easily attainable; they are supported by any sort of rational evidence; and, as being only the dreams of a credulous, sportive imagination, they must soon decline into neglect, if not oblivion. However, in making these remarks, it is far from my intention to express the same animosity as to the mode of treatment issued upon by Dr. Keenish, which issue a question which cannot be determined by reason, but by experience.

OF DELICATE BURNS WITH RAW COTTON.

In America, it is asserted that the best application for superficial burns is raw cotton, finely spread wet, or dried, and put directly on the injured part. (See *Diagnosis of the Deep Cotton in Burns*, in *Porter's Medical Journal*, p. 22; and *Gilman's Treatise and Practice of Surgery*, 3d. ed. 1, Sec. Philadelphia, 1824.) Also, in the *Principles of Gilman*, it is only in superficial burns that this practice answers; but Dr. Anderson, of Glasgow, who has tried it on a large scale, represents it as equally to injure, whether conducted by spreading so much dry, whether superficial or deep, moist or dry, wetted or unwetted. He states, that it has been long applied by the inhabitants of the Greek islands. One of its disadvantages, he says, is, that, except in cases of deep injury, the cure is always slower than without any appearance of inflammation. (See *Glasgow Med. Journ.*, vol. 1, p. 200.) Another is the elevation of the part, always attending the frequent removal of other kinds of dressings; for this is left unchanged a considerable time. Some rise, says Dr. Anderson, is necessary, both in preparing and applying the cotton. For this purpose, it should be

finely sorted, and disposed in narrow flocks, so that it may be introduced; by which means it can be applied in successive layers, and is thus made to fill up and protect the most irregular surfaces. The burnt parts, if wet, are to be washed with tepid water, and the fluid removed by small sponges. Or, if more deeply scorched, they may be heated with a spirituous or mercurial lotion. The system is then applied, layer after layer, until the whole surface is not only covered, but protected at every point, so that pressure and motion may give no annoyance. On some parts, it will adhere without a bandage, especially when there is much discharge; but, in general, a support of this kind is useful. Where the vesicles have been broken, and the skin is scalded, or where there is suppuration, or late suppuration always arises; and, in such cases, Dr. Anderson advises, the discharge may be so great as soon to work through the cotton, and become offensive, particularly in summer, so that it may be necessary to remove the cotton portions. This, however, he advises to be done as sparingly as possible, and being taken to avoid discharging or disturbing the living surface. (See, *cit.*, p. 312.) According to Dr. Anderson, there appears to be a twofold effect from this kind of treatment. The primary effect arises from the exclusion of the air, and the slowly conducting power of cotton, by which the heat of the part is retained, while a soft and uniformly elastic protection from further is afforded. The secondary effect, he says, depends entirely on the shock, or cause, formed by the action, discharging the affected system, or pain, and giving the best possible substance for the best result. "But it may be that the full benefit may be derived, from the stimulus, and to ensure an equable and continued support in the stunted parts, until the new skin is formed, it is absolutely necessary that the cotton should not be removed, except under particular circumstances, and the best advice is sufficiently framed to bear exposure." (See, *cit.*, p. 312.) As Dr. Anderson admits, the theory is of little consequence; and we should not, therefore, attribute a The merit of the practice can be determined only by experience. We have noticed, that Gilman recommends it to superficial burns, and when it is finished, that in other cases the discharge would pass through the unremoved cotton into a moist field mass of scale, putridity, and even suppuration, one can hardly deny that the statement is correct. It is true, the skin may be considered by wetting the cotton in a warm water tub, or bath; but directly this is done, the soft dense property of that substance is lost, and the result is not essentially different from that in which there is not applied, after being wet with the immersion cotton, or other kind applications; and would equally require frequent change. If much constitutional irritation is excited after the cotton has been for some time applied, Dr. Anderson confesses, that it may be necessary to cut out the discharge, or even remove the cotton altogether. "We are then to be guided by the symptoms and appearances, whether to simply cut away the dressings, or first restore a more healthy action in the condition." (See, *cit.*, p. 318.)

The "exclusion of the air" is the true indication in the treatment of burns; but it is imperfectly fulfilled by the dried cotton. In superficial burns, and has long been a domestic application, and can only act in this way; yet when the part is completely covered with a layer of salt, the relief is immediate, and is superficial nature is permanent.

Some surgeons, in this country, treat all kinds of burns on the refrigerant plan; among which Trimmer, Deverge, of Maryland, was among the most prominent. He uniformly directed a water-cure, and was supposed to be at present better, and preserved it until the acute inflammation was subdued, when he used Terebinthine or castor oil as the subsequent dressing. Dr. Keenish's plan is, however, most popular in this country, and almost, in the case of superficial, and the mixture of flannel, of all lime-water are in almost universal use.

As, however, the relief afforded by burns is generally the result of the exclusion of the air from the surface, the modern practice introduced on the system of covering burns with white flour, or other fine white material, will be found by far the most judicious and useful, and the most successful in its results; and that application is adapted to every species of burn, whether occasioned by scalding or actual fire, whether superficial or deep, recent or old, wetted or exposed

were the same practice pursued in a situation in which no air could have access at all, it has been recommended in parts of India through the nostrils, and to remove the air, water has been passed just long enough to serve inflammation, when an attempt is to be made to make the opportunity of the cavity by pressure.

This practice is sometimes approved of by Mr. Brodie on other grounds: he has noticed, that after the whole cavity of the uterus has been converted into an abscess, and this has been cured, no fresh matter enters there again. Hence, he has sometimes been induced to pass into the position a syringe or tube, so (what he deems to be) the base end of a probe, for the irritation of the inner surface of the uterus. This practice I shall not say successfully, on a young woman who was under my care last year. I penetrated the uterus, below the os uteri, and discharged about an ounce of fluid, resembling white of egg. The uterus had existed several months, and the uterus was then evacuated. I kept the patient open about ten days, during which time there was a discharge from it of the same kind of fluid without any tendency to suppuration. I therefore introduced a tent into the opening, by which means the necessary degree of inflammation was excited, the uterus separated, and the disease was more permanently cured, without any serious symptoms. At the same time, I observe, Mr. Brodie is to be perfectly right in maintaining symptoms against the indiscriminate adoption of this practice. Inflammation and suppuration of a large bursa (the ovary) sometimes disturb the constitution so much, that it might be pre-

ferred merely to make a puncture, and keep the patient afterwards perfectly quiet. The pessary is a dissected brass instrument, which he had seen between the lower angle of the scapula and the latissimus dorsi, and which was not much less than a man's head. In this case, death followed the constitutional disturbance excited by a pessary and the union. In another example, seen by this judicious surgeon, when the patient was in bad health, and the due observance of quiescence was neglected, pusillitudo a dissected brass instrument was used followed by death—(Ed. cit. p. 388.)

One or two similar cases, which happened in St. Bartholomew's Hospital, have also been communicated to me. In some instances, the making of too free an incision into the uterus, even has been followed by extensive phlegmonous suppuration of the whole body, ending in death.

When the os of a uterus cancerous is much thickened, and cannot be reduced to their natural condition, Mr. Brodie says, that the uterus, if especially impeded, may be removed with as much safety as is supposed to be. This practice, however, he has only yet applied to the uterus between the pessary and the skin, though he observes to me, of three attempts in particular, which would have enabled him to say more.

Consult *Johnson's Description of the Female Sex*, &c. with remarks on their accidents and diseases, &c. vol. II. p. 570. C. M. Koch, Dr. Maria Ruvig, von Stockholm, &c. and particularly, R. C. Vesalius's *Pathologiae et Chirurgiae Descriptiones in the Joints*, chap. 5, of 2. p. 400. Lond. 1622.

C

CÆSAREAN OPERATION. Called also *Epiotomica*, from *epiota*, uterus, and *reca*, scarre. Puzos, book 7, chap. 9, of his Natural History, gives us the etymology of this operation. "Epiotomica (says he) est sectio perineæ exterioris, sicut Scipio Africanus græcæ naturæ, primæque Cæsaræ uterum mox ante dicitur; quod et cæsar cæsar appellatur. Scipio modo mater uti Scipio per Cæsarum rursus dicitur in-

terum." From this passage we are to infer that the Cæsar operation is extremely ancient, though no description of it is to be found in the works of Hippocrates, Celsus, Paulus Aegineta, or Aulus Cornelius. The earliest account of it in any medical work, is that in the *Chirurgia Galienus de Cæsaribus*, published about the middle of the sixteenth century. Here, however, the practice is only spoken of as proper after the death of the mother, and is alleged to have been adopted only at such a conjuncture in the case of Julius Cæsar.—(See Cap. de *Extirpatione Fetus*.) Vico, who was long revered the close of the eighteenth century, takes no notice of the Cæsar operation; and Pare, who greatly improved the practice of midwifery, thinks this measure only allowable in women who die undelivered.—(De *Morbis mulierum*, lib. 21.) Roux, who was contemporary with Pare, collected the histories of several cases, in which the operation is said to have been successfully performed; and, after the publication of them, the subject excited some general interest.

By the Cæsar operation is commonly understood that in which the fetus is taken out of the uterus, by an incision made through the parietes of the abdomen and womb. The term, however, in its most comprehensive sense, is applied to three different proceedings. It is sometimes employed to denote the incision which is occasionally practised in the cervix uteri, in order to facilitate delivery; but this particular method is named the *external Cæsar operation*, for the purpose of distinguishing it from the former, which is frequently called, by way of contrapposition, the *internal Cæsar operation*. With these views we have seen no allusion the history which is made in the parietes of the abdomen for the extraction of the fetus, when, instead of being situated in the uterus, it lies in the cavity of the peritoneum, in consequence of the rupture of the womb, or in the uterus, or Fallopian tube, in consequence of an extra uterine conception.

INTERNAL CÆSAREAN OPERATION.

Disease, malformation, or a preternatural position of

the cervix uteri, may render this practice indispensable. A scirrhus hardness of the neck of the uterus is the most frequent. When the obstruction is such that the cervix cannot be dilated, and the patient is exhausting herself with fruitless efforts, the parts should be divided in several directions. This has been successfully done under various circumstances. Cases have been met with in which the cervix was procured as opening at all; and yet the preceding operation proved quite effectual. Such is the example which Mr. Simpson has inserted in the third volume of the *Edinburgh Essays*. A woman, forty years of age, became pregnant, after recovering from a difficult labour, in which the child had remained several days in the uterus. She had been in labour sixty hours; but the end of the womb had no tendency to dilate. Dr. Simpson, perceiving that its edges were adherent, and that in opening between them, determined to practice to issue, with the aid of a speculum vast. The incision penetrated to the depth of half an inch before it passed through the substance which it had to divide, and which proved as hard as cartilage. As the opening did not dilate, in the efforts which the woman made, it became necessary to introduce a narrow bistoury in the finger, in order to cut this kind of ring in various directions. There was no hemorrhage; and hardly additional suffering which the patient experienced, arose from the incision of the vagina. As the child was dead, Dr. Simpson perforated the head, in order to render the delivery more easy.

Strong adhesions in the cervix of parturient, may render it necessary for the vaginal Cæsar operation. These sometimes arise as soon as the membranes are ruptured and the waters discharged, so as to prevent the dilatation of the uterus. However, if the contractions seem to continue, and the cervix soon were sufficiently dilated, the child should be extracted with the scissors or by the foot, according to the kind of presentation. On this subject Blandin and Ferrius are of opinion, which was confirmed by the Academy of Surgery at Paris, professor of surgery at Yverdon. The woman was forty years of age, and had been in labour two days. She was in extremely poor health, and could scarcely be known. The pulse was feeble and almost extinct, and her extremities were cold and covered with a clammy perspiration. The edges of the opening, which was about as large as a crown piece, flat, as it were, callous, and hardly had this aperture been dilated, when delivery took place spontaneously. The child was dead. The sym-

Waters were appraised, and the museum agreed to fund a general recovery. Another case, in which the infested curia itself was immediately divided, is recorded by Lachmann, a surgeon in Orleans—(see *Zeit. für Naturgesch. Med.* 1.23, p. 257).

A considerable distention of the neck of the womb, resembling that of a portion of small intestines, may also be a reason for the performance of the vaginal caesarian operation. Thus, such a distention always occasions that of the rest of the uterus, and in the neck of the uterus is usually directed towards that side of the pelvis which is opposite to its flexure, although this is sometimes the case. In the latter circumstances, as the contractions of the uterus in time produce a distention of its neck, which rests upon the bones of the pelvis, the adjacent part of that organ is dilated and pushed from above downwards, so as to present itself in the form of a round smooth tumour, without any appearance of an aperture. Such a case may have had many appearances. Harlequin (alludes to with an instance). A woman in her 34th pregnancy, not being able to endure the distention of the uterus, whose she related, put herself under the care of a midwife, who in her endeavour to deliver, parts during some days. When the accoucher came, on being sent for again, the midwife presented itself in the vagina covered with the womb. The portion of the uterus which contained the fetus, was in a state of inflammation. The os uteri was situated backwards two or six the uterus, hardly dilated to the breadth of a penny-piece, and the waters and loch, discharged a long time. The patient was bled, and emollient Clysters were administered. All sorts of compresses were employed. She was laid upon her back with the joints considerably raised. The midwife had much difficulty in supporting the head of the child, and keeping it from protruding at the vulva, enveloped so it was in the uterus. Notwithstanding each measure, the patient died.

So far as events, more significant, might have been prevented, by looking the witness for years the side against the development of the merger, and employing pressure from above. If these proceedings had failed, by bringing the attention towards the centre of the police, this opening might have been brought into each position by means of the finger, in the interest of the public, and kept as until it was sufficiently distant for the movement to continue.

This is what was done by Bushkovec in one case, where the greatly inflated forehead and the right eye were swollen backwards. The waters enlarged and the facial advanced forward the bottom of the pelvis, flattened in a point of sternum. The whole of the cylindrical labour, which presented itself could be felt with the finger, but an opening was diminishing; after a while the swelling might also be seen on separating the labia from each other and opening the entrance of the vagina. It became necessary to keep the patient restlessly in bed, and to have the finger incessantly introduced; but she was not sufficiently docile to submit to such treatment. Fortunately, the unexpected appearance of two officers of justice, forty-eight hours after the commencement of the labour, had the effect of making her more tractable. It was then too late to become of, for the patient had very become feverish, and, indeed, pained. The abdomen was also so tender, that it could scarcely bear the contact of the clothes. Pelvic symptoms had begun, and the labour could be no longer so continued. Bushkovec made her lie down; and he pressed with one hand on the abdomen, for the purpose of raising the uterus, while with the other he pushed the hand a little way back, in order that he might reach the os uteri, which he now brought with his finger towards the centre of the pelvis, and kept there for some time. The efforts of the patient being now exhausted, she was delivered in about a quarter of an hour. The infant was a very healthy specimen, and the wife had a most favourable temperature.

When the difficulty of the process is such that the process cannot be used, and the engineer and design team is faced with the problem, it is the duty of the practitioner to make the portion of the system that provides the data to the value. This is a case of the design team being the system. A system, however, is not a first class, self-referent system in its own right, but a first class, self-referent system in its own right, that is, a system that is self-referent in its own right, that is, a system that is self-referent in its own right. The system is not a first class, self-referent system in its own right, but a first class, self-referent system in its own right, that is, a system that is self-referent in its own right.

lately occupied by a holy village was protruding heavily and yielded to the pressure of the fingers, once during the labor pains. In extending this tumor he would only feel it, it circumscribed a soft, round, half an inch deep, without any aperture through which the child could pass. Other practitioners, who were consulted about this extraordinary case, were also unable to learn what had happened. They found in the vagina a lacertation, which only afforded a part of the thickness of an ovum. This lacertation was deemed the proper place for making an incision. The operation having been done, the fetus was passed into the uterus in which the child was contained. A large quantity of tarted fluid was discharged. The child passed and passed through the opening, with a slight inclination on the right side. However, having passed his head into the uterus, was unable to find relief for the rest of the body. No particular excitement ensued, and the labor was discharged through the uterus, which gradually closed. In the course of five months the os uteri and neck of the uterus were in their natural position again.—(Lancet, Nov. 18, 1861.)

When the case is a mere laceration of the cornea, or a laceration of the pupillary membrane at the place where it projects into the vagina, the vaginal Casparyan operation is attended with no difficulty. It is performed with a blunt-pointed bistoury, the blade of which is wrapped round with lint to within an inch of the point. The instrument is to be introduced, under the guidance of the index finger, into the opening presented by the strait, and the aperture is to be gently enlarged from within outwards, in various directions. But when the scabrous hardness of the cervix projects on opening it, or when the part of the strait projecting in the vagina is entire, the incision should be made from without inwards, with the same kind of knife. Too much exertion cannot be used, in introducing the instrument, in order that no injury may be done to the child, which has directly behind the substance which is to be divided. No general dissection can here be offered, except that of proceeding slowly, and of keeping the index finger extended along the back of the hand, so that it may be immediately known when the substance of the cervix is cut through, into the cavity of which the finger ought to pass as soon as the knife. But should be necessary to extend or multiply the incision, the cutting instrument should be regulated in a similar manner with the index finger. The cervix after having been divided, the expulsion of the child is either to be left to nature, or to be promoted by the ordinary means. The operation that has been described requires no drainage. If the bleeding should prove troublesome, we are recommended to apply to the vessels a clasp of lint wet with vinegar or spirit of wine.—(See *Obstetric Medicine*, Duguid, &c. L. E.) The shaft of the probe would have to be passed all the way between the cervix of the incision and the upper part of the vagina.—(*Text. des Accouchés* M. D. t. 22. p. 208.)

INTERNATIONAL CRIMINAL OPERATIONS

This is a far more serious operation than that which has just now been treated of, and is the prelude to which the term *Chloroform operation* is more generally used.

There are three cases in which this operation may be necessary: 1. When the father-to-be and the mother died, either in labor, or the first two months of pregnancy. 2. When the father to be died, but cannot be delivered in the usual way, on account of the deformity of the infant, or the hyperemmenic use of the child. 3. When both the mother and child are dying, but delivery cannot take place from the same causes, as in the second case.

In every instance, both mother and child were lined off after the Communist intervention, and the number of followers children attracted—(See *Mother's Journal* of September 1964, p. 112. Also, in *Journal of Democracy*, 5, 1, p. 604, 2, 3, p. 218, in 365. Also, *Mid-County*, and 4, 1, p. 27, 28, 30, 31, and *Sargents Journal*, and 4, 1, p. 27, 30, 31, *Travis*, and 9, 1, and 11, 1.) Very recently in example has been reported, in which Dr. Miller, of Louisville, is also, performed the Communist sessions, and served both the mother and the child. (*Mid-County* for the *Democratic Herald*, 1964, 2, 2, p. 146.)

An instance of similar success is reported by C. H. Greck.—(*Journ. for Obstetrics, &c.* A. 9, p. 13.) Two successful cases, in which both women and children were operated on at the hospital of Münster, by M. Busch.—(*ibid.* Feb. 1823.) Another valuable practical work, one example is reported from Halliwell's Journal, where the author and twelve more all acted by the operation.—(*See Quarterly Journal of Foreign Medicine, &c.* vol. 4, p. 623.)

The most extraordinary case of Cæsaræan operation on record, is one performed by a negro girl on herself, who recovered.—(*See New-York Med. and Physical Journ.* March, 1823.) Dr. Mooney mentions the case of a negro woman in Jamaica, who opened her side with a butcher's knife, and extracted a child, which died of lock-jaw.—*The woman recovered.*—(*See Rayner's Manual of Midwifery, p. 281.*)

In England, the operation has been attended with remarkably ill success; and perhaps there is not one unqualified example, in which the mother has here survived the little Cæsaræan operation. In the third edition of this work, indeed, I referred in the year recorded by Mr. James Barlow, of Cheshire, Lancashire, who sunk in incision into the abdomen, extracted a dead child, and saved the mother's life.—(*See Medical Reports and Researches, p. 151, 178; also, J. Barlow's Essay on Stagnation and Malinjury.*) My friend Dr. Goetz, however, having obligingly communicated to me his doubts, and those of Dr. Hall, respecting the reality of this success having been made (in this instance) on the infant, I was glad to have the opportunity of expressing my entire conviction of the more certain nature of the case taken by these physicians. I am satisfied from the first days, Dr. Hall, that Mr. Barlow was deceived in this case, from the account he gave of the remarkable thickness of the uterus. And I had formed an opinion, that the child had escaped through a laceration of the uterus into the abdomen, enveloped in the membranes, and that he had merely divided the membranes, when he believed he had divided the uterus. Dr. Hall then proceeds to explain the confirmation of his own conviction by those of Mr. Barlow, a very intelligent practitioner at Blackrod, who visited at the operation. "In this, the particulars stated by this gentleman leave no doubt, that the finger had escaped through a laceration of the uterus into the cavity of the abdomen.—(*See Hall's Defence of the Cæsaræan Operation, &c.* p. 72.) The case also referred to by Mr. D. Stewart—(*see Edin. Med. Essays, vol. 5*), where the labour had endured twelve days, and the life of the mother was saved, after the dead fetus had been extracted by a midwife, was also probably of the same nature: at all events, the want of suitable particulars, and the circumstance of the operation having been done by a woman, leave the true nature of the case questionable.

At York, when we speak of the Cæsaræan operation, we mean that in which the panes of the abdomen and those of the uterus are divided by the surgeon, and the fetus extracted, I believe, that as far as the history of the practice extends in this country, it cannot be said, that the mother has ever recovered after such a proceeding; though, more years ago, a calculation was made, that the operation had been done not less than eighteen times in Great Britain; and some there it has been repeated in several instances with the same ill success.—(*See Hædler's Chir., &c.* 2d. Ed. Med. and Surg. Journ. vol. 17.) It is said also, indeed, to have been performed about thirty times in the British dominions.—(*See Rayner's Manual of Midwifery, p. 279.*) Several of the children, however, were saved to have been saved. And in the case operated upon in April, 1826, by Mr. Crockett, of Dorset, the infant was preserved, though the mother sunk eight hours after the operation.—(*See Edin. Med. and Surg. Journ.* No. 36, p. 31.) On the contrary, the practice has proved infinitely more successful; as of 321 cases of this operation to be found in records of medicine, 232 are said to have terminated successfully.—(*See Ellis's Edin. Med. and Surg. Journ.* vol. 8, p. 17.) No doubt, the ill success of the Cæsaræan operation in England was correctly explained by Dr. Hall: "In France and some other nations upon the European continent, the Cæsaræan operation has been, and continues to be, performed where British practitioners do not think it indicated; it is not less successful to-day, before the strength of the mother has been

enfeebled by the long existence and frequent repetition of hemorrhage, though, according to him, and before her life is endangered by the accession of inflammation of the abdominal cavity. From this view of the matter, we may reasonably expect, that ourselves will be more frequent in France than in England and Scotland, where the reverse practice obtains. And, as France, that the value of the operation ought to be appreciated. Who would be so stupid as to imagine, that a recovery after such circumstances, be it generally less successful, as in this country, usually, where the child has laboured for years under inflammation of the uterus, a disease fatal to itself in itself; where, as has been brought into immediate danger by previous inflammation of the uterus, or other contents of the abdominal cavity, or been exhausted by a labor of a week's continuance, or even longer?" Dr. Hall then refers to the opinion of Mr. W. Anderson, that out of sixteen new errors in medicine, or some peculiarity in the constitution of the female of this island.—(*See Hall's Defence of the Cæsaræan Operation, p. 10.*)

The general readiness of continental practitioners to have recourse to the Cæsaræan section has been constantly observed, because they have even operated in cases in which the patients had previously borne children in the natural way. According to Mr. A. W. Anderson, there are not less than seven cases in which the mother has survived the operation, and the child has been born alive. Anderson, who also speaks of the operation, is the Editor of the *Edin. Med. and Surg. Journ.* No. 161, a third by Meier, in *Medic. Ann.* vol. 1, and a fourth in the same journal, by Boerhaave.—(*See Rayner's Manual of Midwifery, p. 279.*) Certainly, if a woman had already borne children in the natural way, the first incision to be made in a strong argument against the necessity of the operation, but perhaps not in its absolute indication, since every thing must depend on the actual dimensions of the lower opening of the pelvis in relation to the size of the existing fetus.

When the fetus is contained in the uterus, and can not be expelled, by reason of the excessive extension in which I have already referred, and embolism, or the practice of sacrificing the fetus and extracting it, if prevented by the vagina, be deemed necessary, the Cæsaræan operation should be practised, since the mother and fetus both perish from the violence of the pains, hemorrhage, convulsions, &c.

For this purpose it is necessary to make an incision in the integuments of the abdomen, and in the uterus. Some have thought that passing the point of the scalpel would be mortal, while others have believed a wound of the uterus, rapidly dangerous. Hence such persons have considered the operation as the principle that religious reasons do not admit taking one life to save another. As the operation of the Cæsaræan operation for the hemorrhage which they are most afraid, indeed, if the uterus were not to contract sufficiently when the fetus and after death was away, the bleeding would prove to be fatal. But when, by means of the Cæsaræan operation, the fetus is extracted, together with the placenta and membranes, the uterus contracts, just as a case after a natural labor. Besides, even when the mother is alive, the operation is not necessary, since the fetus is removed a propensity to deliver itself, and to contract. The womb being delivered of its contents, the incision becomes closed, the vessels contracted, and there is no risk of hemorrhage. The wound itself also heals as usually an organ more disposed to contract; but whenever arguments may be collected, it is enough to say, in this case, after repeated trials, it is equally successful. But, in the case, indeed, as I have mentioned, in which the operation was performed for the hemorrhage which they are most afraid, indeed, if the uterus were not to contract sufficiently when the fetus and after death was away, the bleeding would prove to be fatal. But when, by means of the Cæsaræan operation, the fetus is extracted, together with the placenta and membranes, the uterus contracts, just as a case after a natural labor. Besides, even when the mother is alive, the operation is not necessary, since the fetus is removed a propensity to deliver itself, and to contract. The womb being delivered of its contents, the incision becomes closed, the vessels contracted, and there is no risk of hemorrhage. The wound itself also heals as usually an organ more disposed to contract; but whenever arguments may be collected, it is enough to say, in this case, after repeated trials, it is equally successful.

The possibility of operating successfully on the

living mother was pursued with great perspicacity and accuracy by Simon, in the *M.moires de l'Acad. de Chirurgie*, t. i. 136. Here we are presented with a collection of sixty-five Cæsaræan operations, more than a half of which had been done in thirteen women. Some of these had undergone the operation once or twice; others five or six times. There was one woman in particular who had undergone it seven times, and always with success. This seems to prove, notwithstanding all assertions to the contrary, that the operation for the most part succeeds. But if the life of the mother should not eventually be preserved, this Cæsaræan operation ought not to be regarded as this success; it might always be done when relief cannot be obtained by other means; just as amputation and lithotomy are practised, though they are not constantly followed by success. Would any thing be more cruel than to pluck a mother and her child, and leave them to perish when there is any hope of saving them both? It is true, that when a pregnant woman is free of any internal disorder, and that from the pains and efforts of labour, the fetus is sometimes still alive in the uterus; but in cases of death after difficult labours, and the great efforts made by the uterus to overcome the obstacles to parturition, the fetus is generally dead; and the operation therefore is less likely to be successful.—(See Blandin, *Traité des Opérations de l'Accouchement*, chap. 5.)

It is the opinion of the best writers upon this subject, that whenever a woman dies at an advanced stage of pregnancy, the performance of the Cæsaræan operation is highly proper. The propriety of this practice in such circumstances was known to the ancient Romans; for by a letter of Neræ Prætorius, we know that when pregnant was sufficed, to be buried, and her body had been opened, with the view of preserving the fetus, the use of the sword.—(Sprengel, *Geschichte der Chir.* v. 1, p. 311.) Experience has proved, that when the fetus has not attained the period at which parturition commonly happens, it will sometimes survive the operation a considerable time, and that when it is fully grown its life may be almost happily preserved. Although instances are cited, in which the fetus in utero has been found alive a month or two and twenty days after the death of the mother, little stress should be laid on such prodigies. The operation would be done without any delay. Even then we are not certain of saving the infant's life. In the greater number of instances the fetus perishes at the same time with the mother, and from the same causes. The cases which are recorded of the fetus being extricated alive after the death of the mother, are extremely rare; I shall here only refer to three, two of which rest on the respectable authority of Hippocritus, who was himself the operator.—(Cassiodorus de Conventibus, &c. in *Uterinis*, lib. 2, p. 144–146.) In one of these instances, the operation was done on a woman killed by violence in the sixth month of pregnancy; the child lived six hours; in the other, a fetus was extricated from a woman who had died of typhus fever in the seventh month, and though the operation was not done till she had been dead about six hours, the child was taken out alive, and continued to live full ten minutes. A living child was also taken out of the mother by Vesalius, after her death by typhus.—(Haller, *Obs. Med.* Lugdunæ, No. 74, p. 47.) Sprengel, *Geschichte der Chir.* v. 1, p. 314.) On the 12th of April, 1830, Mr. Green, of St. Thomas's Hospital, extracted by the Cæsaræan operation, from a woman suddenly killed in the sixth month of pregnancy by the passage of a stage coach over her, a fetus that lived 48 hours after its removal from the uterus.—(See *Med. Chir. Trans.* vol. 19, p. 60.) With respect to the contents of the uterus, it is a familiar maxim, *non fœtus fœtendi*, in considering them as mere lifeless organizations; five instances are given, in which the fetus was taken out of the mother three days or twenty-four hours after her death, and still continued to live. Graafius says, that at Sydenham in the course of eighteen years, the operation had been pursued twenty times with the same circumstances; that at Grægorius, thirteen children were saved out of twenty-two mothers who had died pregnant; and that in twenty-four years, at Montpellier, twenty-one children were preserved in the same manner.—(Kempner's *Icones*, Feat. 1768, 166.) As Sprengel remarks, he has to admit, except from this system, that in binary pregnancy was generally fatal,

If the mother should happen to die in labour, and the neck of the uterus were sufficiently dilated, or disposed to be so, an attempt should be made to accomplish delivery in the ordinary way; for examples have occurred in which women, supposed to be dead in this circumstance, were in reality alive. Hence we find that the Senate of Venice, in 1608, enacted a law, by which practitioners were liable to punishment in case they neglected to operate with as much caution as a pregnant woman supposed to be dead, as on a very objectionable and false to be observed were death issued by the same government in 1700.—(Nott, *Med. et Chirurg. Antiquæ*, p. 108, the Venice 1721.) Ponsard, *Obs. de l'Opération Cæsar.* p. 15, 16, 17, 18, 1778.) A law to the same effect was likewise made in 1719, by the King of Sicily, who directed the practitioners of death to these medical men who omitted to perform the Cæsaræan operation on such women as died in the advanced stages of pregnancy. In the doctoral case of the Duke of Savoy, 1718, the following case, continuing the propriety of such cautions, was recorded by Rucellandus, surgeon to the military hospital at Besançon. This practitioner having been sent for to a woman, to whom no assistance he was unable to proceed till five hours after her apparent death, he found the child with which she was covered, deceased, and perceiving that the body retained its suppleness and warmth, he tried whether the uterus could not be extricated in the ordinary way, which was immediately effected as soon as the feet were put forth. The first endeavours to save the child were very unprosperous; but after a few hours they had the desired effect. As the woman continued in the supine position five hours afterwards, Rucellandus recommended that she might not be buried before her limbs were quite cold and stiff. He observed that the candidate for Jura University was also ordered to life. This remarkable case happened on the 20th of June, 1719, and both the mother and child were living in the period which Rucellandus published the above account.

Supposing, however, delivery in the ordinary manner to be impracticable, in all events the Cæsaræan operation might be performed with the same cautions as if the mother were alive, only one caution being made for the purpose of saving the uterus.

Almost all the inextinguishable choruses to delivery originate from the bad construction of the pelvis, depending upon nature; though they are not an inevitable consequence of it, since there are women extrinsically deformed, in whom no impediment of the pelvis exists, while it prevails in others whose shape is but trivially disordered. An examination of the dimensions of the pelvis is the right mode of ascertaining whether there is really such an impediment to parturition. In order that the dimensions may not be an obstacle to delivery, the distance between the upper rim of the sacrum and the os pubis ought to be three inches and a half; and the distance between the tuberosities of the ischia and between each of these protuberances and the point of the os pubis, five, three inches. Women have indeed been known to be delivered without measure, although the first of the above distances was only two inches and a half; but then the heads of the children were so situated, that the great diameter was nearly eight inches, while that which extends from one point to the other was reduced to two inches five or six lines, and the infants were *trifles*. If they are to be born alive, they must be taken out of the womb by the Cæsaræan operation; for the latter proceeding should never be adopted without a certainty that they are *trifles* living; for whose death they may be corrected in a way that is attended with much less risk to the mother.

It is not always in any patient so uncertain with certainty whether a fetus is alive or dead, or on death. It has entirely ceased to move, after being affected with a violent motion, the probability is that it is no longer alive. But to be certain, instead of examination is necessary, which may be performed in two ways. One consists in pressing upon the uterus, through the pliability of the abdomen. If the child lives, such pressure makes it move, and the motion can be plainly felt and distinguished. In the other method, one hand is employed in pressing upon the uterus externally, while with the fingers of the other hand passed up the vagina, corresponding pressure is also to be made. The uterus is likewise to be moved as far as possible, in order to make use

status is even. When no decisive indications can be trusted obtained, it becomes necessary to rupture the membranes, if they have not already given way, introduce the hand into the uterus, and put a finger inside the child's mouth, for the purpose of making it turn its breech. This finger may also be applied to the nape of the head, so as to determine whether this organ is lying; and the vaginal cord may be caught, in order to determine whether there is still a presentation, or not. When none of these precautions furnish successful information, the conclusion is that the child is dead, and no attempt is indicated, unless the satisfaction of the parts be such that the best chance be given to the system, in which case, the Cæsarean operation is indispensable.

The first and most direct judgment respecting the dimensions of the pelvis? And how can we know whether that measure which extends from the upper edge of the sacrum to the os pubis, is long enough to allow the passage of the child? The proper conformation of this part is known by its thickness and equality of the lips, both on the transverse and perpendicular direction; by the projection of the pubis; by the moderate depression of the sacrum; by an extent of four or five inches from the middle of this depression to the bottom of the sacro-coccygeal; by an extent of seven or eight inches from the superior process of the last lumbar vertebra to the highest part of the most vertebra, is a woman moderately fat; and by their being an adhesion of each to each, is seen between the two anterior superior spines, protrusion of the os coccygis.

These general indications, however, are insufficient. In order to acquire more correct opinions, double compasses have been employed. The handles of the first being applied to the top of the sacrum and middle of the trans vertebra, three inches are to be deducted from the distance indicated by the instrument, viz. two inches and a half for the thickness of the upper part of the sacrum (which is said to be constant in subjects of every size), and half an inch for that of the os pubis. In women who are exceptionally fat, some lines must also be deducted on this account. Hence, when the last thickness of the pelvis measured in this direction is seven inches, there will remain four for the distance from the upper part of the sacrum to the os pubis, or the extent of the lesser diameter of the upper aperture of the pelvis.

For taking the measurement internally, a kind of scissor has been invented by Connolly. It bears a considerable resemblance to the instruments employed by shoemakers for measuring the foot. It is passed into the vagina, with its two branches approximated, until one arrives opposite the anterior and upper part of the sacrum, when the other is to be drawn externally, so as to be applied to the pubis. The distance between the branches is judged of by the graduations on the instrument. This was named by its inventor a pelvimeter. According to Sabatier, it is not always easy to place it with accuracy; its employment is attended with some pain; and there are particular cases in which it cannot be used.

Instead of this instrument, the celebrated Baudouin recommended a means which seems to be very easy and simple. The index finger of one hand is to be introduced into the vagina to the upper part of the projection of the os pubis. The finger, during the radial edge turned forwards, is then to be inclined obliquely till it touches the arch of the pubis. The point of contact being then marked with the opposite hand, the length from the point in question to the end of the finger is to be measured. This length, which indicates the distance between the sacrum and the bottom of the symphyseal pecten, usually exceeds that of the lesser diameter of the pelvis by about six lines. Baudouin acknowledges that this measurement is not exactly accurate; but he believes it will do very well, because, unless the measurement of the pelvis be extreme, two or three lines hardly indicate difference in the facility of parturition.

The following is the description of the pelvis of the woman twice operated upon by Dr. Leboyer. The os pubis, which should be on the same level with the promontory of the sacrum, were found perpendicular to it; so that the child necessarily required the abdominal circumference to its own weight, little is probability in compressing the thighs. The os coccygis, nothing could be felt of the child by external ex-

per exposure. The os coccygis, instead of showing the pelvis, was hidden by a vesicular sac, which forms a kind of cushion to the child in parturition, denoted nearly horizontally backward. A symphyseal cyst of this pelvis, with a few other particulars, may be seen in a modern publication.—(Med. Chr. Trans. vol. 21, p. 189.)

The pelvis may be every where well formed, and yet present an extraordinary obstacle to delivery, in such an obstacle, however its dimensions, which extend to the bones which compose this part of the skeleton. Passing out with a ease of this description is a woman who had such a case. The os coccygis was drawn from one of the two points. A vesicular cyst, filled with the head of the child in the upper aperture of the pelvis, eight weeks or the same effect which it was directed, and could be pushed out of the way, so as to make room for the fetus to pass. Baudouin mentions a swelling of this kind. It was on or seven inches long, and an inch and a half in width. The extremity of it, which was as large as half a beef's leg, had a heavy foot, and contained four well formed teeth, the rest of the mass being oblong. It had descended into the lesser pelvis, below the promontory of the sacrum, and a little to one side. It might have been taken by an incision of this last bone. The instrument consisted sixty hours, and the possibility of performing the Cæsarean operation was under consideration. Baudouin was sworn to this proceeding. He was concerned turning the child and extracting it by hook, because he thought that the pelvis was sufficiently spacious to admit of delivery. The os coccygis was cut at three inches from the lower part of the sacrum, and four inches from the lower part of the sacrum. The fetus was soon easily extracted. The assistance of the forceps was necessary to get out the head. The child was well born. The mother, exhausted with numerous travelling efforts, only survived between fifty and sixty hours. Baudouin was of opinion that a decisive regimen also tended to increase her death.

Among the innumerable obstacles to delivery may be reckoned such a displacement of the uterus that this viscera protrudes from the abdomen and forms a hernia. The records of surgery have preserved some examples of this extraordinary occurrence. Twice has the Cæsarean operation been performed on one of the two cases, the woman survived so long that hopes were entertained of her recovery. Indeed, as Sabatier observes, why should not the operation succeed in such a case, where the uterus is only moved by the ligaments, and there is no occasion to raise the abdomen, just as well as other instances in which it is indispensable to divide the uterus, and open the cavity of the belly? In the other case on record, delivery was effected in the ordinary way, after raising the abdomen and keeping it in this position with towels skillfully placed, or by making pressure on the uterus, which had the beneficial effect of making this organ resume its proper situation.

History shows the absolute necessity for the Cæsarean operation under certain circumstances, a minute to consider the proper time for performing it, the legitimate preparatory means, and the method of operation.

With regard to the time of operating, practitioners do not agree upon this point: some advising the operation to be done before the membranes have burst and the waters been discharged; others not till afterward. The arguments in favor of the first plan are, the facility with which the uterus may be opened without any risk of injuring the fetus, and the hope that the uterus will contract with sufficient firmness to prevent hemorrhage. The advantages for the second mode being, that in operating after the discharge of the waters, there is less danger of the uterus falling into a state of relaxation in consequence of having suddenly emptied after being fully distended, and that this point does not demand so extensive an incision. Hence they recommend, as a preliminary step, to open the membranes. Whatever conduct be adopted, it is essential that the uterus should be support and supported, that the cervix uteri should be effaced, and that the os tunic should be sufficiently dilated to allow the fetus to be discharged; and at the same time, safe perhaps, if the operation is not to be done till after the escape of the waters, there ought not to be too much delay, lest the patient's strength should be exhausted,

and the violent effects of labour should bring on an inflammatory state of the parotid or the testis.

The government is using the victims and bloodies to pretend that it is necessary to insist upon it. This pretension is only particularly obvious in regard to the list of those officers, which has been known to have been made after the Germans as to control the southern part of it. Everything had been done to prevent this organization in a broader area than it was operating. The machine would then be moved and presented itself through the same defeat of the opposition in the character of the modern.

[illegible]

For the purpose of understanding the operation, the student should be placed at the edge of her back, well supported; her chest and head should be comfortably raised, her knees should be somewhat bent, and held by assistants, one of whom might be at the elbow, and from there downwards, so as to compress, in some degree, the swelling of the uterus, and prevent the pulsation of the bowels. These things being attended to, the engagements are to be decided with the convex-sided trowel, in the usual of at least six inches. The plane and direction of the incision differ with different operators.

13. The most accurate method, it was customary to make the incision between the outer edge of the testis, namely, a line drawn from the umbilical superior mesenteric process of the testis, to the junction of the base of the third rib with the cartilage. Thus cut very lightly a little below the umbilicus, and was continued downwards as far as an inch above the pubis. After the integuments had been drawn, the various appendages, and peritoneum were cut, and the uterus cautiously opened. The left index finger was then introduced into this vagina, the wound of which was dilated by removal of the probe-pointed bistoury.

This manner of operating is subject to great inconveniences. The place where the incision is made is the situation of the placenta, the fibres of which have a different direction, and, as compressing, separate the edges of the wound, and make it gape. The considerable blood-vessels which ramify there, may be the source of serious bleeding. The births can scarcely be that accurate unless reliably than any where else. When the position of the uterus is oblique, and when, consequently, the edges of the incision are turned forwards and backwards, and its surfaces to the right and left, the uterus will be made in one of the lateral positions of the uterus, when the trunk of its blood-vessels are known to be twisted, and sometimes even the Patauian tube and ovary may be cut. The fibrous of the uterus are not transversely, so that the edges of the incision are apt to gape, instead of being in contact. The last circumstance may the more readily permit the uterus to escape into the abdomen, inasmuch as the uterus is cut nearly through its whole length, and there is no cavity in which they can accumulate in order to be discharged through the os of the uterus.

The latest skin has been frequently considered the most eligible place for making the incision. As Professor Williams writes, it was the method adopted by Boileau and Delorme, and it has the recommendation of Sir John Dalrymple, because these are better parts to be cut, and when the wound is exposed, an incision parallel to its principal fibres may be made in the middle part. Boileau thought that this plan of operating originated with Flaminio and his son, a surgeon of Cremona. A German surgeon says: "Incisions made across cutaneous vessels give rise to hæmorrhage and more pain; first, because, upon abdominal wounds, the vessels may, by constant contraction, or constant external pressure, be closed; in this case, much as incisions are better here, which began a little above the umbilicus and extended to within an inch and a half of the navel." He afterwards divided the fat, muscles, and peritoneum in order to get at the viscera, the exterior part of which was removed, the wound being made rather in the body than the flange of the viscera. Dalrymple still has a great deal more to

[illegible]

This mode of operating, as Sabatier observes, gives more scope of vision than the plan first described; but he agrees that such scope has not been realized by experience. Though the operation may have been more easy, he believes that the edges of the wound in the skin, and those of the incision in the peritoneum have had no tendency to rejoin in a state of proximity to each other, because the linea alba is the point in which all the large vessels of the abdomen principally sit, and because the contraction of the clamps necessarily takes place from above downwards. Sabatier alleges that the wound in this vessel has been found to refuse to join of its sides, for the same reason as occur in operating on one of the sides of the abdomen. He also states, that the intestine has been conveyed under the integuments of the upper part of its plexus, and that the pressure of the bladder renders the wound soon being carried sufficiently far down. Perhaps, may be, a part of these inconveniences which depend upon the contraction of the apertures, and the want of this organ in its natural state, might be avoided by extending the incision to its highest part. Randolphe has advised this plan with the view of preventing the fatal adhesions in the abdomen, which frequently follow this operation. Sabatier, however, has doubted whether in operating in the same site, the wound can be carried high enough. Besides, he maintains, that this operation would not prevent the wound from getting, nor the greater tendency of the intestines to be extricated by the abdomen than to retract into its cavity, and be discharged through the os tunicæ. (*Medical Operations*, tom. 1, p. 273, 274.)

In this country (where, indeed, the Cassinetti operation has proved most successful) the same note is preferred, I believe, by the majority of practitioners. That the method is not always attended with the desirable objections urged against it by Kottwitz, is quite certain: the epicurean published by Dr. Thompson is a deliverer proof of this assertion.—(See Edin. Med. and General Journ. vol. 4. p. 176.)

There is a third method of performing the substituted Newman operation. It consists in making a transverse section five inches in length, through the posterior end of the chest, between the scapulae and the spine, and in a situation five or six inches from the axilla, at the level of a elevated position of the scapula. This has been recommended by Lawson, as a published method, Novelski of Moscow has published the position of Lawson. Parry, in 1882, has published a modification that the method had been used.

carefully positioned by different persons before the mother, and especially in one instance, which was particularly remarkable, as, in consequence of the first incision having been made too high up, it became necessary to make a second one, which extended, of course, from the other. However, according to Skene, Lacroix has an objection as if he had accepted his plan, since he has given a better explanation of its advantages than any of the predecessors.

The wife on which the operation was to be done is, in itself a matter of indifference. But if the liver or spleen were in position, one ought to avoid it. Also, if the uterus were to incline more towards one side than the other, it would be proper to operate on the side where the vessels could be most conveniently exposed. The patient being put in a prone position and held by assistants, and her abdomen kept steady by an assistant, who must apply the point of his hands to the sides of the uterus, the integuments, muscles, and peritoneum are to be divided with the usual precautions. The uterus is then to be opened, and the wound in it enlarged to the requisite degree, by means of a probe-pointed bistoury. Should the placenta present itself, care must be taken not to lacerate it, for fear of opening one of the arteries of this mass, which communicates with the umbilical arteries of the child, or of leaving a portion of it in the uterus; but it should be separated, in order to facilitate bringing the incision into its circumference. The child is next to be extracted. This part of the operation is subject to no general rule. Delivery being accomplished, we are recommended to introduce through the vaginal canal, speculums, in order to lessen spasm, and which cut the coagula. This method is preferable to that of clearing out the uterus with the hand. Scudder most properly condenses the plan formerly advised by Blandin and Haisse, of passing up the neck of the uterus a catheter for the purpose of washing out the lochia, as well as the absurd proposal of employing a sponge to push them away. Should the lochia not pass readily upwards, we are recommended to introduce the finger occasionally into the cervix, until, as to force, it finds the coagula, which may obstruct it.

Scudder observes, that nearly all authors who have spoken of the Cesarean operation, whether performed at the sides of the abdomen, or in the lower part, have advised keeping the edges of the wound in the skin, muscles, and peritoneum together, by means of the interrupted or twisted suture, care being taken to place at the lower part of the incision a suture in order to prevent adhesion, and leave a free issue for whatever discharge may take place from the abdomen. Others have been content with recommending the use of adhesive plasters and the twisting ligature.

Scudder condemns sutures as painful and irritating, and he states that the other women only act upon the skin, without holding the object in view, because the integuments have no fixed point, and the divided muscles tend to contract. He asserts us, that in the last mode of operating, the edges of the wound may be brought into contact by merely laying the patient upon her side. Besides, he remarks, that there are not many muscular fibres cut, those of the transversals being only separated from each other. He affirms, that this manner of operating also favours the approximation of the edges of the wound in the uterus, in consequence of the uterus contracting more extensively in the perpendicular direction. It is likewise asserted, that as the uterus has only been opened at its upper part, it affords no middle and lower portions a large cavity, which does not communicate with the abdomen, and in which the lochia may easily accumulate, and afterwards be discharged by the natural way. The only advantage advised by Scudder is, a large, slight, convergent, and a moderately tight bandage round the body. These are to be changed when soaked with the current or discharge. In this country practitioners would not hesitate to drag the edges of the wound as much as possible together, by means of strips of adhesive plaster. But, though they may not act with so much effect in this situation as in many others, they undoubtedly assist in preventing the separation of the vagina, which is the kind of laceration the upper part of the uterus, if possible, by the best method. I have no doubt there are many who would be introduced by Scudder. In this country, the last method of operating has also been tried.

Mr. Wood, of Manchester, performed the Cesarean operation, in a case in which post-mortem was prevented by delivery of the foetus. The incision was made nearly in a transverse direction, on the left side of the abdomen, about five inches in length, beginning at the umbilicus. This part was fixed upon bones, the sides of the child could be felt there, and it was evident that no intestine was interposed between the abdominal parietes and the uterus. There was scarcely any effusion of blood, either from the external wound or from that of the uterus, though the time was made directly upon the placenta. Instead of dividing the placenta, Mr. Wood introduced his hand between it and the uterus, and, laying hold of one of the child's knees, exerted the fetus with ease. His hand readily passed between the placenta and uterus; this produced no hemorrhage, but was very successful. He drove, in the whole quantity of blood but not an exposed artery or vein. After the uterus was emptied, the intestines and ovaries protruded at the wound. These having been reduced, the integuments were brought into contact with sutures and adhesive plaster. This operation, however, did not save the woman's life; she died on the fourth day after the operation—(see Med. and Physical Journal, vol. 3.) As I have already explained, the ill success of the Cesarean operation in England has been such, that not a single case has yet happened in which the use of the method has been preserved after the child was truly extracted from the womb by Caesarean. The probable reason of this circumstance I have already stated. Alford, however, the surgeon of the prison some years ago, has been successful in this country, the operation having been often given as to it with the same look of the mother and child of which of some interesting example was recently published by Dr. Lown, of Zurich—(see Med. Jour. Trans. vol. 3, p. 11.) And in vol. 11 of the same work, may be read a case in which Dr. Meyer, of Hanau, lately saved a woman by the operation, but the fetus was dead. I have an example in which Dr. Spahn, in 1801, preserved the lives both of the infant and mother, and another interesting relation of two Cesarean operations performed by Lomax, on a woman who being at Nines, in Bohemia—(see also Nichols's *Annals of Gynaecology*, &c. vol. 3, part 1, p. 189.) In 1800, Dr. Schlegel, of Mannheim, likewise operated on a woman who recovered, notwithstanding the wound became supplicated, and she is still living, with a healthy child the situation of the wound—(Schlegel's *Archiv. des Anatomie*, p. 155, *Ann. Paris*, 1805.) The Cesarean section has been successfully performed by Grisel, at Berlin, the woman and child both having been saved—(Journal, &c.) And besides this and various other instances of success already referred to, another was afforded in April, 1802, in the person of Vanderburgh—(see *Review* &c.)

In the *Western Journal of Medical and Physical Science* for April, 1803, Dr. Dickinson, of Newbern, Ohio, reports a successful case of Cesarean operation, performed in 1807. He was under the necessity of performing the operation in midwifery, on the spot of the moment, without a consultation, and under most unfavorable circumstances. After he had divided the uterus and the placenta, which was attached directly under his incision, he found it impossible to remove the fetus, until he had divided the uterus of the thick part the upper lateral vessels, when it was extracted with facility. The mother recovered entirely in four weeks.

The necessity for the operation arose, from inflammation of the uterus and vagina. His examination of the patient per vaginam, on the day previous, Dr. Dickinson found the whole depth of the vagina but two-thirds of a finger's length, the anterior wall being a kind of septum passing obliquely upwards, from behind backwards, leaving about one and a half inches between it and the cervix, and the distance in time would not be discovered by the most minute examination. He notices to the operation, that it is an artificial laceration, and he describes a kind of tube extending from the uterus to within three-fourths of an inch of the cervix, sometimes, improving below, and probably entering, slowly into the vagina. He offers to insert in the mother in which conception had taken place. The woman was returned at the time, but has since lived with a husband two years, but no conception has

taken place. This is the first and only instance of the successful performance of the Cesarean section in the United States.—*Note.*

OF OPERATIONS WHEN THE FETUS IS EXTRA-UTERINE.

Delivery cannot possibly happen in the ordinary way, when the fetus is situated in the uterus, or Fallopian tube, or in the cavity of the peritoneum. However, there are many instances recorded of ventral protrusion, whilst the mother survives, the dead fetus having been discharged by fragments out of an abscess in the parietes of the abdomen. A remarkable case under Mr. Gearing, in St. George's Hospital, I had the opportunity of seeing a few years ago, in which the child was discharged piecemeal from an abscess on the right part of the abdomen; and I have lately seen another case under Dr. Hickey, of Westminster, in which portions of bone and a great deal of matter have been voided through the vagina, though the swelling is altogether on the right side of the abdomen.

Practitioners are occasionally called upon to do a very singular operation in the Osseous, when the child has passed into the cavity of the peritoneum, in consequence of the rupture of the uterus. Unfortunately, such an accident is not uncommon, and though the chance of it may not be obvious, holding a more terrible truth than the latter itself is entirely proven, and has no share in producing the misfortune. The symptoms, by which the event can be known, are not always easy of misconception. When, however, the pains have been violent; when the face, after being excessively swollen, has been relieved by a kind of relief; when the countenance loses its colour, the pulse grows weak, and the extremities become cold and covered with a cold sweat; when the abdomen is generally flat and only partially affected with a swelling, accompanied by the fever, which either continues to grow, or is dead and malignant; when the patient complains of a distressing sense of heat above the belly; and lastly, when the child strikes from the touch of the abdomen; it is regarded that the uterus is lacerated. If the child has passed completely into the abdomen, putrefaction is the only poison. Should a part of it, however, yet remain in the uterus, it may be extracted with the aid of the forceps, or the local promote, or by the leg, provided only the upper part of the body be in the abdomen.

Bulloughs quotes three instances of putrefaction, performed on account of the rupture of the uterus. The first is that inserted by Thomas Dobson, in the *Journal de Médecine*, for May, 1760. Every preparation was made for a natural labour, when, after an extremely violent pain above the upper and left part of the uterus, the child disappeared. Dobson opened the abdomen, though not till some hours after the accident. The infant was dead; but the mother experienced no ill effects after the operation, except such as are usual after ordinary labours.

The second and third cases were communicated to the French Academy of Surgery in 1775, by Laribon, a surgeon of Orleans. He practised the operation twice on the same woman with success. In the first instance, he opened eighteen hours after the rupture of the uterus. The child was dead. An ill-conditioned abscess formed near the wound; but the patient got quite well in the course of six weeks. She was pregnant again the following year, and the uterus was now more relaxed. Laribon now had recourse to the operation without delay. The child delivered some signs of life, but soon died. The mother got only six weeks; but afterward became pregnant again, and had a favourable delivery.

In a singular case, I have alluded to the case in which Dr. Locher, of Zwick, saved both the mother and child by the Cesarean operation, performed in the last case. After her recovery, a small part of the wound, not extending to three lines in length and breadth, required a ligature to be quite healed, though no particular inconvenience was experienced from it. Some time afterward the uterus grew very tight, and a portion of membrane protruded, which was removed, with a piece of brown cane, and was again removed. The edges of the wound were then brought together, but a small superficial ulcer continued in spite of every effort to cure it. In 1795, the year following, that in which the Cesarean operation had been performed on her, she became pregnant

again, and the child particularly which happened during position, was an increase in the size of the protruding ulcer, which became three inches in width. The son, however, was delivered with ease, and the arguments well supported with adjuvant plaster. On the 23d of May, she was seized with labour-pains; and about seven in the evening, she complained of at once of a very acute pain, and at the same moment voided a considerable quantity of blood from the vagina. On examining by this passage, nothing was discovered; but, when the hand was applied below the navel, in the line of the old wound and under the ulcer, a discoloured firm swelling was felt, covered by the child's head, of which the uterus was partly dissipated. Dr. Locher naturally concluded, that the uterus had burst, so as to allow the child to escape, and the hemorrhage was thus easily explained. A repetition of the Cesarean operation was deemed unnecessary. The place of the wound was discoloured by the wound swelling, caused by the child's head. An incision six inches in length, was made into the abdomen, where a quantity of coagulated blood was found. When this had been removed, the membranes presented themselves, containing a black line; and after they had been opened, the head of the child immediately appeared. The navel-string was cut round the neck, which was then compressed by the opening of the uterus. The child expired as soon as life. The placenta came away during the attempts to transverse the child. The mother recovered, and there was little bleeding. This patient, after a good deal of indisposition, and occasional approaches to a perfect recovery, died at length attacked with inflammation of the stomach and bowels, and died on the 9th of July. The uterus was found contracted to a small size, with an opening of about the size of an almond, on an anterior surface, with a rounded ragged edge. This aperture, Dr. Locher speaks, had remained ever since the first operation, and had allowed the escape of the child in the second labour; a circumstance which may be doubted, as the hemorrhage followed the period when the uterus had been lacerated, and the position indeed lay in one place particularly suited herself. (See Med. Clin. Trans. vol. II, p. 162, &c.) An almost incredible case is related of what may be called a Cesarean birth, effected solely by the powers of nature, and, as would appear, by a sudden rupture of the vessels and rupture of the abdomen, after the patient had been in labour three days.—(See *Lancet and Old Physical and Literary*, vol. 5.)

A laceration in the uterus, or the wound made in this tissue in the Cesarean operation, may give rise to dangerous and even fatal symptoms of strangulation if any of the arteries mistake themselves into the peritoneal opening. When such an occurrence happens in the performance of the preceding operation, the intestine must be directly withdrawn and replaced. If the accident were to happen, when the child is extracted in the natural way, the lower is to be pushed back into the abdomen from the uterus. Were the occurrence to take place several days after the operation, Sabatier inquires, what ought to be done? A surgeon is said to have pushed back the intestine from the uterus as late as the third day. Sabatier thinks, that attempt could not be done. In this circumstance, that dilemma solves the question suggested by Pagni, namely, that of opening the abdomen and withdrawing the lower from the place in which it is incarcerated. But there are serious objections to this proceeding. There is no certainty that the intestine is incarcerated, though it were so; the adhesions which are soon formed, would frustrate the design of the operator.

Cesarean has not only been recommended for cases where the child has passed into the abdomen through a rupture of the uterus; it has likewise been advised by instances, in which the fetus has grown in the Fallopian tube, away, or cavity of the abdomen. Here, indeed, the operation deserves to be called Cesarean; for, in addition to the situation in the tube and cavity of the abdomen, it is necessary to open the pouch in which the child is contained. The instances of conception in the Fallopian tube are not uncommon. These in the uterus and cavity of the peritoneum are more rare. Singular conceptions, that rest of the uterus reported to be of the lower kind, if strictly examined, would have been found to be in reality conceptions in the Fallopian tube.

Extra-uterine conceptions hardly ever arise at maturity. However, the fetus found in the Fallopian tube has elements here known, to attain the form of nine months, and then die, either from the impossibility of its expansion, or from the insufficiency of the nutriment afforded it. The pouch in which it was contained, and the neighboring parts, have then inflamed, and after becoming extremely congested by morbid effusions, have ruptured. The abortion has taken place, partly at some point on the circumference of the tube, and partly into the rectum; and the dead fetus has been discharged perineal with the "water."

In other examples, the fetus, instead of giving rise to the abortion, has become entangled with the enveloping membranes, and retained in this state many years, without any other inconvenience to the patient than what depended on the size and weight of the tumor within the abdomen.

Next frequently, however, the pouch containing the fetus bursts about the middle of the ordinary period of gestation, and the third passes into the cavity of the peritoneum. At the same moment, the blood-vessels supplying the surface of the containing parts usually pour forth into the abdomen so much blood, that the patient generally die in the space of a few hours.—See a case by Dr. Clark in *Trans. of a Society for the Improvement of Medical and Chirurgical Knowledge*. Also another, advertised by Dr. C. Hall, in *Med. Clin. Trans.* vol. 4, p. 243.

Two facts of this kind fell under Salazar's observation. The woman was in the end of the ninth month of pregnancy. Excepting a swelling, which affected only one side of the abdomen, and frequent dragging pains in this cavity, there was no evidence of any thing extraordinary. In other respects the patient was well. They were both, all on a sudden, attacked with extremely acute pains which lasted two or three hours. A most violent effusion that the rest was followed by entire ease. The abdomen swelled, and he was, as it were, flat. Atypical morbid warmth diffused itself over this part of the body. The skin lost its color. Almost continual syncope occurred. The pulse was feeble and uncounted. The whole body was covered with a cold sweat, and the woman died. The rapid course of these symptoms rendered it impossible for Salazar to be of any service. The patient was actually dying when he was called to attend. The examination of their bodies evinced, that the abdomen contained a large quantity of blood; that the intestines lay on the intestines, connected with the late-mentioned Fallopian tube by means of the uterine artery; and that the tube itself, which was strongly congested, presented as other tissues, except that which depended on the afterbirth.

There is nothing that approaches an extra-uterine pregnancy with sufficient certainty to justify any positive conclusion respecting the nature of the case, before the ordinary time of parturition. In many women the general blood inclines to one side, and uterine congestions become more dragging pains, which may depend upon other causes. Things, however, are different when the fetus has lived to the ordinary period of parturition, and the woman is attacked with labor-pains; because, besides the unambiguous signs of the presence of a child in the abdomen, the vessel is empty, and is little changed from its common state. Should women, like Salazar, have recourse to the Cæsarean operation, just as if the fetus were in the womb? But we are sure, that the peritæum which contains the child, will contract itself like the uterus, and thus the incision which is in contemplation, will not give rise to a fatal hemorrhage? Would it be easy, to separate and remove the whole of the placenta? How could the placenta, analogous to the fetus, find an outlet, and would not its extravasation in the abdomen be likely to prove fatal? Salazar thinks, that the risk which is to be encountered, is equal less when things are left to nature. The child, indeed, never survives a period. It will either give rise to abortion, with which it will be discharged in the uterus, or it will remain for a length of time in the abdomen, without any urgent symptoms. Salazar also advises attention to the great premonitions of an infant's life, and expresses his opinion, that there can be no safety in deciding what could easily be avoided. Happily, practitioners are not often placed in circum-

stances as Salazar, and extra-uterine conceptions mostly perish before the end of the common period of gestation. We have then only to attend the efforts of nature; rather by promoting expunction, if it should seem likely to occur, by making a suitable opening, in enlarging one that may have formed spontaneously, by extracting such fragments of the fetus as present themselves; by breaking the bones when their size and position there in the uterus, are likely to be an obstacle, where the abortion takes into the rectum, and lastly, by employing suitable injections.—(*Salazar, Of Accidents Operative*, c. 2.)

An extremely remarkable case of extra-uterine conception was related a few years ago by *Wagner*; the woman having at length passed into the bladder by all exertions, and caused such affliction we rendered assistance into that measure indispensable, with the view of extruding the parts of the fetus lodged in it. The operation was done above the pubes; but the internal mischief already existing was so great, that the patient did not recover.—(*Vierteljahrsschrift Naturforsch. der Medicin*; *Rastatt*, 1823, nos.)

Grove, p. 411, relates a case of ventral conception, in which instance the Cæsarean operation was done, in the child preserved. A lady, aged thirty-one, had a tumor in the groin, which was at first supposed to be an epiplocele, but an unusual pulsation was perceptible in it. In about ten weeks the swelling had become as large as a potato of bread. Grove, assisted by the lady, opened the tumor. He first discovered a sort of umbilical sac, whence issued a gulf of a length of three feet. The sac was dilated, and a foetus fetus found, about half a foot long, and large in proportion. It was perfectly alive, and was baptised. After tying the umbilical cord, the placenta was found to be attached to the parts just behind, and near, the abdominal ring, but it was easily separated. Grove does not mention whether the mother survived; but the thing would not be very surprising, considering the situation of the fetus. *Bertrand* says, he was unacquainted with any other example of the Cæsarean operation being done, in case of extra-uterine fetuses, so as to save both the mother and infant. This eminent man considered opening, in such cases, as the greatest that the physician could not be acquainted from the viscera, in which it might be done, or, if left behind, it could not be drained, without such inflammation and suppuration as would be mortal. But if, in addition to such objections, says *Bertrand*, the operation has been proposed by nature, and promoted by nature, we may conclude, that this depends on the difficulty of judging of such progressions, and of the time when the operation should be attempted. His opinion of the question the difficulties which have been indicated the containing dead portions of the fetus, and the fetus's case, who operated without expecting it met with a fetus at all.—(*Bertrand, Traité des Opérations de Chirurgie*, chap. 5.)

Whatever the Cæsarean operation, or pessary, has been performed, the practitioner is not unreasonably endeavor to prevent inflammation, and the wound, and approve any antiseptic symptoms which may arise; he should also prevent upon the mother to suckle the child, or order that the lacta may not be too copious; and, after the wound is healed, she should be advised to wear a bandage, for the purpose of limiting the extension of a ventral hernia, of which, according to *Wagner*, there is a considerable risk.

The following case of extra-uterine conception is here inserted as being particularly singular in its kind. As such case is to be found referred to in *Wagner's* *Art. Med. Digest*, see in any of the numerous periodicals which contain the profession. It occurred in the person of Mrs. Corrie and Harlow, of Georgia, and was communicated to Prof. Parvins, of New-York. The subject was a negro woman, aged 35 years. On the night of the 23d of Jan. 1829, she was taken in labor. There occurred no doubt that she had arrived at the full time of labor. Her labor-pains ceased, she was attended to for a few days for dropsical symptoms, after which she suffered greatly. On the 3d of February, she was again taken in labor. The pains, however, immediately entirely ceased, and after five weeks she expired. On examination after death, the following facts presented themselves. In the first place, Mrs. Harlow and Corrie drew off from the abdominal firm and a half-gallon of an extremely turbid and bloody fluid. On opening the abdomen, the first thing that

presented itself was the child, climbing itself across the abdomen; its head in the right, its feet in the left, hypochondriac region; its back immediately to the left-thigh of the mother. It was as large a child as that of three had ever seen at birth, and perfectly formed. The circumference of the neck alone, about six inches in length, and inserted into the shoulder when without the intervention of a placenta. The uterus was about the size of an orange; its coats very tough thickened and inflated, with a small quantity of a thin bloody fluid within its cavity. The abdominal viscera were all diseased, save the bladder. The liver retained its normal shape and position, but looked more like a mass of glue than a soft solid organ. The spleen had gone into a state of complete ossification. As to the stomach, there was not the slightest change left. The bladder appeared to be the only viscus that had escaped unscathed from this disposition in nature. The lungs had simply adhered in one solid mass from the stomach to the uterus, and to the posterior and lateral portions of the abdomen.—(*See New-York Med. and Phys. Journal*, vol. i.)

The case of extra-uterine fetuses in which Dr. Mackenzie of New-York operated with success, is often referred to.—(*See Lond. Med. Society's Trans.*, vol. 6.) This interesting case confirms the views of those who believe in the entire production and perfusion of the human fetus extra-uterine.—(*See Taylor's Med. Biography*.) But even this opinion is not confined to the United States, and therefore does not detract from the claims of Mr. Richardson, who opened the uterus itself.—(*See the preceding note*, p. 221.)

Gastricmy has been performed for the removal of extra-uterine fetal several times in America, with complete success.

Mr. Wm. Baylis, of Virginia, member of the Royal College of Surgeons, London, succeeded as early as 1776, in removing an extra-uterine fetus from the abdomen, after it had lain there two years. He thus preserved the life of a valuable woman, who was otherwise would have fallen into the grave, with hectic fever and the most distressing symptoms.

In 1798, he repeated the operation with the like success on a servant woman of Mrs. Washington, Fairfax Co., Virginia. In the publication of these cases in the *N. Y. Med. and Phys. Journal*, vol. 1, Mr. R. has performed a valuable service to the profession, in the judicious remarks with which he accompanies the report.

In the same work, Dr. J. Anthonio Smith, now Professor of Anatomy in the University of New-York, has published a case in which he performed this same operation in fact, in the city of New-York, with the most satisfactory result. I have not been able to find any other cases of success in this operation in this country, except those of Dr. Mackenzie, Mr. Baylis, and Professor Smith, and must refer to the journals I have named for their interesting details.

The following cases of Cæsaræan operation, are extracted from the *N. Y. Med. and Phys. Journal*, vol. 3, for 1822; and as two of them were well performed, and the other accomplished by an illustrious female surgeon, they will be found interesting to a high degree. The recovery of these women should be regarded as extraordinary events, rather than as astonishing encouragement easily to attempt this great and dangerous achievement.

In the *Memories* of Jan. 26th, 1822, says Dr. S. M'Chesney, I was called upon by Mr. Ripps of Nassau, to assist with Dr. Bauman in the case of a servant girl, who, having been in a dangerous situation, had been removed to his house, and found the patient to be a girl sixteen years of age, one month black. She had a fine pale complexion of 18th or 19th years. Dr. R. informed me, that she had a wound in her abdomen, near the centre of the epigastric region, from which he had extracted a full-grown fetus, that was in part perfused, together with a considerable portion of her intestines. The placenta having two twisted cords attached to it, he had removed from the same office, and had also introduced her hand into the uterus per vaginam, &c.

In examining I found an irregular incision of about four inches in length, extending in a diagonal direction, as regards the abdomen, about two inches above the umbilicus, and an incision of about two inches in length nearly a right angle with the former, extend-

ing towards the sternum. The lower part of the abdomen was considerably distended with blood.

Observations were in the first place directed to the examination of the blood contained in the abdomen, which was partly effected by a change of posture and slight compression. "We then brought the lig. of the uterus in contact by the interrupted suture, dressed it with lint soaked with emollient ointment, and secured the whole with a broad bandage. After administering an anodyne, we left her for the night. I did not see her again, but was informed by Dr. R. that she never had any very violent symptoms.

The second day he bled her, gave her a cathartic, and pursued the antiphlogistic regimen a few days, when the febrile excitement abated. An ordinary dose of food was then resorted to and in a few weeks the patient was perfectly recovered.

The circumstances attendant on the solution of the wound were these. While the lady was at dinner, she went a distance of perhaps fifty rods from the house, and placed herself on a snow-dripping fence, where she was first discovered by her master in the act of covering something with snow, which afterward proved to be a naked child. As soon as she perceived that she was observed, she immediately ran to the house, with the second child hanging on at the waist, together with a considerable portion of her intestines; led by her nose and large vessels, which were the instruments she had previously prepared for the operation, and shortly began to complain.

I should judge from the appearance of the blood upon the snow, these being three several places where she evidently stepped, that the incision was made hurriedly proceeding the rupture of the membranes, and that the first child was contained per viam naturalem, the third pain after the rupture.

As many of the greatest discoveries in every department of science are made by accident, or without any particular pre-arranged design, may not the conduct of this desperate girl give a useful hint for an improvement in the Cæsaræan operation, consisting in a division of the uterus diagonally, near the fundus, instead of the ordinary method?"

The following is the case of Anne O'Neal, inserted in the *Medical Essays and Observations* published by a Society in Edinburgh, by Mr. Duncan Stewart, Surgeon in Glasgow, in the county of Tyrone, Ireland.

Anne O'Neal, aged about thirty-three years, with a poor father near Chesham, and mother of several children, in January, 1793, took her infant pains; but could not be delivered of her child by several women who attempted it. She remained in this condition thirteen days; the child was judged to be dead after the third day. Mary Donnelly, an illiterate woman, but sensible among the peasant people for extracting dead births, being then called, used also to deliver her in the common way; and her attempts not succeeding, performed the Cæsaræan operation, by cutting with a razor, first the remaining parts of the abdomen, and then the uterus; at the aperture of which she took out the child and membranes. The upper part of the incision was an inch higher, and on a side of the cervix, and was continued about six inches downwards in the middle between the right os uteri and the Anus, after she had the lips of the wound together with her hand, and one went a mile and returned with with and, the constant fluids which issues out. With these she joined her lips in the manner of the Irish exposed ordinarily for the hum-lip, and dressed the wound with water of eggs, as she told me some days after; when, led by curiosity, I visited the poor woman who had undergone the operation. The age was estimated with accuracy of the patient's own recollection.

In about twenty-seven days, the patient was able to walk a mile, on legs, and came to see my father's house, where she showed me the wound covered with a vesicular; but she complained of her belly being distended towards the right side, where I observed a tumour as large as a child's head, and showed it distended with the liver, after which I gave her some medicine, and advised her to drink the decoction of the rubicary pines, and to support the side of her belly with a bandage. The patient has enjoyed very good health ever since, manages her family affairs, and has frequently walked to market in this town, which is six miles distant from her own house.—(*Edinburgh Med. J.*)

In the year 1818, a negro woman (belonging to the

and the completion of this substance with the fluid from the vessels.

This state of the scrotum was of several of twenty years' duration, and had been gradually increasing, the tumour increasing as the scrotum increased in size. The extent known to us was of which it could be ascertained.

From its size and weight, as well as the long-term nature of the disease, he became desirous to have a removal if practicable and proper. The health being otherwise good, and the tumour appearing to more than the original nature, but was maintained that the operation should be performed.

An incision was made across the root or base of the scrotum, beginning on each side of the upper part of the penis, at a point a little above the scrotum, so that some enlargement of this part of the penis in a diseased state was also removed, and carried down to the perineum, leaving an irregular portion of the scrotum below at about an inch in length. Continuing cutting through the diseased integuments and the subcutaneous cellular membrane, the capital root of cutaneous was readily discovered and divided. The vessels of the neck were unobscured by extensive dissection, leaving the incision extended on each side several inches. Numerous arteries were cut during the dissection at the perineum, as well as several large veins in the perineal sac.

The perineal portion of the scrotum was covered by a very considerable amount, but it was altogether unobscured by the incision. A few nerves for the scrotum, and only to be cut from the perineal portion. Light feelings of heat, tingling, and a few slight pains applied for the first few days, followed by slight pain in the lower part of the back.

Respiration and circulation being well established, the rest of the operation was finished by the use of various straps.

The complete recovery from the operation, and the reproduction of a scrotum, was not attended by any inconvenience. Three years have now elapsed, and he enjoys excellent health, being occasionally obliged to take for a week or two a few grains of the sulphate of ferrous, to restore the action of his stomach, which, before the operation was performed, threatened to become an organic disease. — *Doyle*

CALCULI IN THE INTERIOR OF THE EYE.

See Eye, &c.

CAL-CIN, *new bone*, or the substance which grows in and cements the ends of a fracture, and for the production of bony matter.

1. The old surgeons believed callosities to be a bony transverse concrete, a thin, porous, red bone, the extremities of the fractured osses, which was soon hardened into bone. They always described it as an "enlargement of the bony part," and imagined that it issued from the ends of broken bones, in this form, sometimes too profusely, sometimes too sparingly. The rupture of bones, bones, and the breaking of callus, they compared with the gluing together of two pieces of wood, or the welding of a broken pot. — (*J. Ford*). They also conceived, that callosities sometimes flowed into the joints, so as to form a piling, permanent protuberance. They imagined that callosities were a space which constituted a dangerous period of time, and they therefore had fixed days for removing the bony part of each particular fracture. They supposed, that as callosities might be expressed by a firm and well-colored bony, and its bony substance covered by pillars and compresses; that it might be softened by fomentations and oils, so as to allow the bone to be set again. All these notions were mistaken; and their absurd doctrines have been the source of death to the thousands of patients, from Hippocrates down to Dr. Allen and Mr. Gooch.

2. By Gooch and Dehaene, however, a second doctrine was established, which treated the formation of callosities as the production and secondary bony, which were supposed to be two solid pieces, and the fracture, the substance between them being absorbed.

3. A third opinion, maintained by Blandin, and the last modern authority, is, that the process of nature, in the production of callus, bears a great resemblance to the changes which take place in the union of the soft parts.

A bone is a well-organized part of the living body; that matter, which keeps its vessels parts together, is of a gelatinous nature. The phosphates of lime, in which a bone owes its firmness, is deposited in the interstices

of the gelatin, undergoing a constant change and renovation. It is incessantly taken up by the absorbents, and secreted again by the vessels. It is this constant absorption and deposition of earthy matter, which keeps the bones firm, and enables it to grow with the growth of the body. It is this increasing activity of the vessels of a bone which enables it to resist itself when it is broken or dislocated. In short, it is by various forms of new secretory process, that bone is formed at first, is supported during health, and is renewed in all cases of very ossification. Bone is a secretion, originally deposited by the arteries of the bone, which arteries are constantly employed in growing it. Callosities are not a vascular growth, deposited merely for filling up the interstices between fractured bones, but it is a superabundance of bone and perfect bone, furnished with arteries, veins, and nerves, by which its earthy matter is continually changed, like that of the contiguous bone. Indeed, there could be no connection between the original bone and callosities, were the latter only the inorganic concrete, as it was formerly supposed to be.

Notwithstanding the more accurate opinions now entertained concerning callus, the expression is still very common, that the slightest fracture will destroy callus, while it is being formed. But, says Mr. John Bell, it is an ignominious error, proceeding merely from the state of the parts and having little or no effect. For, when callosities form, the perfect constitution of the bone is restored; the arteries pour out from each end of a broken bone a gelatinous matter; the vessels by which that gelatin is secreted expand and multiply in it, till they form between the broken ends a well-organized and animated mass, ready to begin anew the secretion of bone. Thus, the ends of the bone, when the bony secretion commences, are merely in the same condition, as soft parts which have recently adhered; and it is only when there is a want of consistency in the tissue, or when a want of elasticity makes inequalities, then these remaining their secretions, that callosities are imperfectly formed. Thus is the reason why, in certain constitutions, is patients affected with syphilis, or pregnancy, or fever, or in any great disorder of the system, or while the wound of a compound fracture is open, or callosities are prevented. — (*John Bell's Principles of Surgery*, vol. 2, p. 560, 561) There are some of the latter statements in conflict, or not, will be seen in the article *Fractures*.

For some time the secretion of earthy matter is interrupted; the young bone is soft, flexible, and of an organization suited for all the purposes of bone; but lacks the delicate and unobscured; not a more concrete, like the crystallization of a salt, which, if interrupted at the moment of forming, will never form, and leads to the decomposition of a slight accident, and to be entirely destroyed by being even roughly moved or shaken. In perfect callosities in soft and yielding; it is figurative in its composition, so that it is not very hardy injured, and in its organization it is so perfect, that when it is hurt, or the bony secretion interrupted, the broken bone heals, just as soft parts adhere, and thus the callosities become again entire, and the process is unobscured.

In consequence of the above circumstances, if a bone is broken a second time when the first fracture is nearly cured, the bone suffers more easily than after the first accident; and Mr. J. Bell, even asserts, that when it is broken a third and a fourth time, the bone is still weaker. In these cases the bony growth, it is true, is still greater. In these cases the bony growth, it is true, is still greater. In these cases the bony growth, it is true, is still greater.

Callosities are said to be more vascular than old bone. Mr. J. Bell mentions an instance of a bone, which had been broken twelve years before he reported it, yet the callosities were colored singularly red. When a recently formed callosities is broken, many of its vessels are destroyed, but some are only elongated, and it is very large, that its whole substance is torn. It is easy to control, or modify the continuity of the vessels will be restored in a broken callosities, when we reflect on its great vascularity and the vigorous circulation excited by the arteries in vessels already accustomed to the secretion of bone. These vessels state why a broken bone callosities is more readily united than a fractured bone.

While the ends of a broken bone are connected together by a flexible substance of earthy matter, callosities, Dr. Blandin calls this bond of union the pro-

This odorless and destructive disease enters the most important parts, wherever their nature may be, to enter into the system of action. The skin, the cellular membrane, the muscles, and the peritoneum, all become affected if they are in the vicinity of cancer. This very striking circumstance demonstrates, as we have seen, says Mr. Abernethy, from several other theorems. In what the author calls *circulatory cancer*, the disease is propagated along the absorbing system; but the parts immediately in contact with the diseased glands do not assume the same diseased action. Neither is the tabulated system from the disease spread along the skin, but destroys that part only which covers the diseased glands. According to Mr. Abernethy, a disposition to cancer existing in the surrounding parts, before the actual occurrence of the diseased action, may be a circumstance noted by Mr. Hunter, since from the following rule in practice: That a surgeon ought not to be satisfied with removing merely the diseased or actually diseased part, but that he should extract every more part of the surrounding substance in which a *diseased disposition* may probably have been seated. In consequence of this communication of disease to the contiguous parts, the skin soon becomes ulcerated, and attached to a cancerous tumor, which in the manner is fixed to the muscles or other part over which it is seated.

As a carcinoma tumor increases, it generally, though not invariably, becomes tropical upon its surface, so that this inequality has been considered as characteristic of the disease. A festering pain is common; but it is not experienced in every case without exception. It is also a symptom attending other tumors, which are called *carcinoma* in situ, and it cannot, therefore, be deemed an infallible criterion of the nature of the disease. (*Laboratory's Surgical Works*, vol. 2, p. 39, &c.)

A hard and painful glandular swelling, having a disposition to become cancer, says Hunter, is the essence, the analogue and strenuous denotation of scirrhus. The disease is not regularly attended with swelling; sometimes scirrhus parts diminish in size and shrink. Scirrhus is not a characteristic property; the many tumors which are not scirrhus, are exceedingly indurated. The disease is not always seated in a gland; it frequently attacks structures which cannot be called glandular; and hard glandular swellings are not often seen, which are not parts of scirrhus. The disposition to cancer cannot be interested among the marks of scirrhus, since it is not discoverable till carcinoma has actually commenced. Its formation is not an inevitable occurrence; and other causes become carcinoma in which we can hardly say the term scirrhus. (*Laboratory's Surgical Works*, vol. 2, p. 39, &c.)

With regard to the observation that carcinoma is not a essential character of carcinoma, Mr. Bell says that in carcinoma only in a certain sense. "It is true (says he) that there is not always an increase of the dimensions of the whole breast; on the contrary, true carcinoma is often accompanied with a contraction and diminution of the general bulk. But when it is true of the breast or mamma is not true of the tumor; for the proper structure of the gland either shrinks or is diminished; and sometimes the surrounding fat is diminished or absorbed, so that the whole mass is less than the natural breast, or that what the breast was before the commencement of the disease. But still the diseased part is properly a tumor; there is no use in treating mass, a preternatural growth, or new mass, corresponding to the old definition, *carcinoma* signification. But harder, and as respect to the above mentioned fact is not always diminished in carcinoma tumors, but sometimes (says the contrary; and this difference is not without sometimes (proceeds a variety in the extent of the tumor, which there is some in the disease actually in the internal structure. Sometimes, thus the diminution of fat, the irregular tabulated structure of the disease will be apparent to the eye and to the touch; while in another patient the breast will be large, soft, and smooth, only marked more than usually with large blue veins, and having as clear like a new day in the eyes of the breast." (*C. Bell, in Med. Obs. Pract.*, vol. 12, p. 223.) These observations fully agree with those which were mentioned in the communication of cancer have needed the to

Scientific surgeons ought undoubtedly to have a disposition mounting when they employ the term scirrhus; the word is generally used more vaguely; and, perhaps, influenced by its etymology, surgeons call an extensive number of various morbid infestations scirrhus, which are not all of a malignant or cancerous character.

I have always considered scirrhus as a diseased hardness, in which there is a propensity to carcinoma, therefore, and a greater likelihood to become that state in any other kind of diseased hardness, although the skin may occasionally not break during life and a few scirrhus infestations may have been removed.

Though Hunter states that the disposition cannot be removed till carcinoma has actually taken place; though Mr. J. Hunter and Sir E. Home affirm that other infestations and tumors may terminate in cancer; though Mr. Abernethy states that scirrhus and every other tumor may and is not malignant, and such an equal cancer is actually (J. Hunter, *Works*, p. 33); yet it is now well ascertained that in all these instances, the changes which precede carcinoma are distinct from the scirrhus or the state of a true malignant scirrhus.

The coloring of the skin, the dull, leaden color of the integuments, the knotted and matted feel of the disease, the continued stinging pain in the part, the fixed attachment to the skin above, and muscles beneath and in the breast, the retraction of the nipple, form so striking an assemblage of symptoms, that when they are all present, there cannot be the smallest doubt that the breast is a scirrhus, and that the disease is about to acquire, if it have not already acquired, the power of communicating the surrounding parts and the lymphatic glands in which the absorption of the diseased part takes place.

As Sir Everard Home has observed, the truly scirrhus tumor, which is known to be capable of changing into the true open cancer, when allowed to increase in size, is known to be hard, heavy, and connected with the gland of the breast, and, when moved, the whole gland moves along with it. The structure of a scirrhus tumor in the breast is different in the various stages of the disease; and a description of the appearances exhibited in the three principal ones, may give a tolerable idea of what the changes are which it goes through previous to its breaking, or becoming what is termed an open cancer.

When a scirrhus is made of such a tumor at an early stage, provided the structure can be seen to advantage, it presents the following appearance: the center is more compact, harder to the feel, and has a more uniform texture than the rest of the tumor; and is nearly of the consistency of cartilage. This middle part does not exceed the size of a silver penny; and from this, in every direction, like rays, are seen ligamentous bands of a white color and very narrow, leading to the section, like so many extremely irregular lines passing to the circumference of the tumor, which is bordered with the substance of the surrounding part. In the intersection between these bands the substance is different, and becomes less compact towards the outer edge.

On a more minute examination, numerous ligamentous bands, of a lighter appearance, form a kind of net-work, in the meshes of which the new-formed substance is enclosed. This structure accords with what Dr. Baillie describes as presenting itself in cancerous diseases of the stomach and uterus.

In a more advanced stage of the tumor, the whole of the diseased part has a more tabular structure; no central part can be distinguished; the external edge is more defined and distinct from the surrounding gland; and the ligamentous bands are different directions are very apparent, but do not follow any course that can be traced.

According to Mr. C. Bell, it is like ligamentous bands which produce the retraction of the nipple, by contracting between its ducts and destroying its spongy texture. (*Med. Obs. Pract.*, vol. 12, p. 223.)

On dissection, Mr. Astley Cooper observes, that the breast is now solid mass like cartilage, with very little vascularity except at its edges, and internally dense. When the breast has acquired any magnitude, however, there is generally an opening in it, in which case it has the appearance of being from within and empty. In the progress of the alteration it is very vascular, and bloody before it is not with. The absorb-

every kind of emotion, this, excite, irritate, excite, &c., and the integuments become affected before the distention produced by the size of such swellings becomes very considerable. In some cases, the skin may become congested, discoloured, and pained.

Some tumours may be harder and denser than a few scirrhi, but otherwise it is exactly the same.

As every induration and tumour may assume the cancerous shape, and even end in cancerous degeneration; and as some true scirrhi, when not irritated by improper treatment, may continue stationary for years, the occurrence of actual cancerous events proves that the preceding rule was that of scirrhi. The only criterion of the latter disease is derived from the assemblage of characters already specified: we trace the peculiar pecking, and speedily notice discoloration of the skin, as other appearances, considered separately, bear any trace of discrimination.

The white ligamentous bands around a scirrhus form a very characteristic mark of the compound, at least as it appears itself in the female breast; but these bands do not extend till the disease has been removed. Hence, the probability of taking away a considerable portion of the substance, surrounding every scirrhus tumour. Were any of these white bands left, the disease would inevitably recur.

Mr. Pearson has observed that with an imperfect proof of a primary swelling in an abscessed gland, and (says he) if a longer experience shall confirm this observation, and establish it as a general rule, it will afford mutual assistance in forming the diagnosis of this disease.—(*Pract. Observ. Medico-Chirurg. Complément*, p. 2.) Sir E. Home, however, has given the following:—If an abscess which seemed to form in the breast, is not of the fungiform shape, situated between the nipple and the axilla.—(*Obs. on Cancer*, p. 105.) The position laid down by Mr. Pearson, that when the disease originates in these glands, it is rarely to be met with a cancerous matter, may yet be generally correct.

OF CANCER IN THE STATE OF ULCERATION.

According to the observations of Mr. Abernethy, the diseased skin covering a cancerous tumour of the breast, gradually elevates before the swelling has attained any great magnitude; a large tumour is then produced in its substance, rising by a struggling and partly by an insidious process. Sometimes, when cells contained in the tumour are by this means laid open, their contents, which are pulpy matter of different degrees of consistency and various colours, fall out, and its external base becomes more and more elevated. The discharge takes place with a velocity which would almost induce belief, that it was hardly removed from the process of secretion. When the diseased substance, as it were, exhausted themselves, an attempt at reparative efforts to take place, similar to that which occurs in healthy parts. New flesh is formed, constituting a fringe of granular tissue, as a periphery of the diseased centre by which it was produced. This diseased fringe occasionally elevates scirrhi. But though the centre of the disease are thus enlarged, though they may in for some time increase and increase, they never cure, nor does the part ever become healthy.

In the very white, the disease extends through the surface of the absorbing vessels. These glands become affected at a considerable distance from the original tumour. The progress of carcinoma is an insidious and gradual in the sense in that which has been already described. The disease is unaccompanied from any gland or inflamed surface till all the cellular structure is affected. Some regard to under the cutaneous, at the lower part of the arm, and lower part of the chest, become discoloured. Occasionally, a stria or two become elevated higher up in the arm, and frequently one of the course which the absorbed fluids would take. As the disease continues, the absorbed glands, in the situation of the diseased tumour, gradually become affected. In the advanced stage of carcinoma, a profusion of small tumours, similar in structure to the original disease, form at some distance, in so become a kind of irregular scirrhi nodules.

The most frequent observation is with nodes, the pain and erythema which the disease induces, accompanied by the contraction which it assumes with the formation of

absorption in those parts in which the vessels leading to the diseased glands belong. Towards the termination of the disease the patient is generally affected with difficulty of breathing and a cough.—(*See Abernethy's Surgical Works*, vol. 2, p. 72, &c.)

The general condition of the patient is vividly described by Mr. C. Bell. After mentioning the hectic fever which precedes her, he observes, "The countenance is pale and anxious, with a slight hectic heat; the limbs have become pinched, the eyes and nostrils slightly well; the pulse is frequent; the pains are severe. In the lung tumours the pain is stitching or sharp; in the opposed surface it is burning and severe. When the lungs are exhausted, entered near the body, especially in the back and lower part of the spine; the legs and shoulders, &c. Successively the glands of the body, and those about the already become diseased. Some pains about the arm of the arm at the axilla, in which an abscessed system, and has no connection. At length, there is a cessation and weakness of digestion. A locking cough sometimes occurs. Several scirrhi swell through the skin; the pulse becomes rapid and thready; the surface indurated; the breathing anxious; and so the end."—(*Med. Ess.* Trans. vol. 12, p. 223.)

One of the most deplorable effects occasionally resulting from cancer is, in most a finality of the tumour that those of the backbone, known by the most infrequent nature, as merely scirrhi in fact, Mr. Astley Cooper mentions several examples of this fact. In the collection of St. Thomas's Hospital in the thigh bone of a Mrs. Edge, which broke out her merely rising in bed; and also the thigh bone of another cancerous patient that was fractured by her falling in bed.—(*Lectures*, vol. 2, p. 184.) Other cases are recorded by surgical writers.—(*See Prolegomena* Oration.) It seems that the carcinoma indurata is deposited in the structure of the bone, as the scirrhi of Mrs. Edge above mentioned fully illustrate; and in the reports at St. Thomas are two curious specimens of diseased bone, in which a scirrhi of the bone is absorbed, and without inferiorly deposited in the space produced by absorption. In the first specimen of carcinoma, described by Mr. Abernethy, the part is peculiarly hard, and rarely admits considerable magnification. He states, however, that there are varieties, and speaks of another case in which the indurated carcinoma was not only pale and glassy, and a specimen in the first was the least in this state, not doubt whether the disease be several stages of carcinoma. The extension of the tumour is also much less hard than in the specimens first described; yet it is more compact and heavier than most other diseases of the same kind which are not carcinoma. If the history of the disease accords with that of carcinoma; that is to say, if it begins in a small distinct and regularly, and insidiously, around its periphery, and gradually, and insidiously, around its periphery, leaving produced in various parts nodular projections, knobby, the disease will almost invariably be found to be carcinoma. The skin will soon adhere to one or more of these projections; it will thicken and expose the subjacent parts; and the future progress of the disease will accord to that of the harder and smaller specimen, except that the abscesses are much less liable to be affected.—(*Id.* vol. 12, p. 223.)

The edges of a cancerous ulcer are hard, ragged, and irregular, very painful and painful in different ways, being sometimes turned upwards and backwards, and on other occasions forwards. The white surface of the ulcer is usually irregular; in some parts there are considerable elevations, while in others there are deep excavations. The discharge for the most part is a thin, discoloured, frothy, and is often composed of such a degree of acrimony as to corrode, and even destroy the neighbouring parts. In the most advanced stages of the disease a good deal of blood is often lost from the diseased vessels. A burning heat is invariably felt over the elevated surface; and this is the most tormenting symptom that attends the disease. These shooting, burning pains, which are generally very distressing in the local state of the complaint, become later a great deal more so. Normal blood and nervous fluids are not always situated in glandular parts, the situation of such some fluids some assimilation in the diagnosis; for as there are many cancerous affections of the bone and of the brain, as in all the rest of the body, &c.—(*Id.* vol. 12, p. 223.)

of a traumatic cause, it has been observed, however, "that we scarcely ever see glands diseased and of the course which the absorbed matter would naturally take, though they are affected in this manner in diseases which may be propagated by contagion."—(Alcock's Surg. Works, vol. 2, of *Transactions*, p. 75.)

Undoubtedly there is some connection in elderly persons; but, according to some writers, in the young coming from the disease. Mr. J. Barnes has seen it frequently noticed and attended with a fatal issue. In children of five years old, he sometimes took instances of the eye being affected in such manner, though, from the late observations of Mr. Warton, we may more reasonably suspect that these examples were really cases of cancerous nodules. An instance, in which a cancerous character of the breast began at the age of fifteen, is related by Sir E. Home.—(Ibid., on Cancer, Art. p. 26.)

Mr. Astley Cooper has frequently seen the disease at all ages between thirty and seventy. He does not recollect seeing less than two cases in which the nature of the tumor was decidedly scirrhus. In persons under thirty years of age. He has seen one case in a patient aged thirty-three; another in an individual of eighty-two; and he has treated an abscessed scirrhus from a person seventy-three years old, who got well. According to Mr. Astley Cooper's experience, the disease does not speedily occur above the age of fifty. The majority meet with it between thirty and forty, and often called scirrhus, he says, are only simple chronic enlargements, not deemed to require active, and not requiring removal.—(Lectures, &c. vol. 2, p. 185.)

Age makes a great difference in the whole class of cancerous tumors; and as Mr. C. Bell has remarked, the same disease distinguishable by various signs will run its course rapidly, and with every symptom aggravated, in a woman of thirty-five, while it will remain stationary for years in a woman of sixty or seventy.—(Med. Clin. Trans., vol. 12, p. 116.) Mr. Astley Cooper also states that when it occurs in very advanced age, it is slow in its progress, and does not in general shorten life.—(Lectures, &c. p. 255.)

According to Mr. Astley Cooper, married women, who bear six children, and single women, are more subject to this complaint than such as have large families. He thinks it very probable that the natural change which the breast undergoes in the secretion of milk has some power in preventing this disease. But he admits that the circumstance of a woman having large children is not a perfect security against the complaint; and he knew one individual with this disease who had been pregnant seventeen times.—(Ibid., vol. 2, p. 272.)

This gentleman's experience confirms a remark made by other writers, that grief and morbid anxiety seem frequently to have a great share in the production of scirrhus of the breast.—(Ibid., vol. 2, p. 273.)

TREATMENT OF CANCER.

Cancers have sometimes been supposed to be a general disorder of the system; sometimes merely local affections. This is a point of much importance in practice, for if cancers are originally only local affections, no operation can be made to relieve them. They who think that cancer is a constitutional disease, will have much less confidence in the operation, which they may even regard as useless, perhaps fatal, inasmuch as it may convert a local into a general cancer, or bring on the affections in some other part.

Some practitioners, however, reject the doctrine of cancer depending on constitutional causes; and Sir E. Home's comments, in opposition to the opinion, have been laid before the reader. When cancer breaks out again in the same part, after the performance of an operation, it is often owing to some portion of the disease having been dissipated left behind, so as the operation having been just of no use. How likely it is that some of the cancerous disease may be left terminated by the operation, is obvious on considering the manner in which the white bands, resembling flowers, shoot from the surrounding fat, and that when the fibres of the mammary glands are cancerous become also generally affected. After operation, it may be allowed that the disease is supposed to be all apparently so destroyed, and consequently removed, as no recurrence may be feared, perhaps with equal probability, as the continued operation of the same unknown cause which originally produced the first cancerous mischief. Mr. Astley Cooper said lately after very experienced men,

both of the past and present time, consider cancer as decidedly a complaint connected with a peculiar state of the constitution. But if this be true, it may be asked, how can any cure be expected from the removal of the part, as the continued operation of the same constitutional cause must necessarily re-produce it? And as they sometimes do, as already mentioned, the effect of the accident of any portion of the disease not being completely removed with the knife. However, experience proves that the operation frequently affords a relief cure, and another surgery is afterward attended, which is unquestionably a proof of the recurrence of a scirrhusous body; a case in which frequently no other part is afterward attacked, though the constitution is changed.

From the description which Mr. Astley Cooper has given of the constitution of persons destroyed by scirrhus, it must be inferred, not only that the disease is constitutional, but that the hope of radically curing it, either by medicine or an operation, being very often laid in advanced cases. He says, that a scirrhus in the breast is generally accompanied by several smaller nodules of the same character in different parts of the mammillary structure. He remarks the depositing of the same disease matter in the axillary glands, and these above the clavicle. On the left side, he says, the latter sometimes press upon the separation of the thoracic duct. According to his observation, the glands behind the cartilages of the ribs, when the disease is on the external side of the nipple, are generally diseased. The axillary glands on the other side of the body he has also seen in the same state. The lungs are often found enlarged, and adherent to the pleura; scirrhus is infused in the pleura, and the pleura itself studded with scirrhusous nodules. He also describes the liver, stomach, uterus, and bowels as participating in the morbid change.—(See *Lectures*, &c. p. 185, and 4.) Under such circumstances the utility of any treatment must be obvious.

Half a century ago, the accounts given of the results of operations for cancers were so depressing, that they deterred many patients from undergoing a timely operation; which for cancerous complaints, is the only remedy with which we are as yet acquainted, offered to such patients. As Mr. B. Bell remarks, the great authority of Dr. Alexander Monro must have had an insuperable influence even with practitioners, in making them much more backward in undertaking the extirpation of cancers than they otherwise would have been. "Of near sixty cancers," says he, "which I have been present at the extirpation of, only four patients remained free of the disease at the end of two years; three of these lucky people had scirrhus tumors in the breast, and the fourth had an ulcerated cancer on the lip."—(Edin. Med. Essays, vol. 3.) Dr. Monro also observes, that in those in whom he saw the disease relapse, it was always more violent, and made a quicker progress than it commonly did in others on whom an operation had been performed. Hence, he questions, "whether ought cancerous tumors to be extirpated, or ought the palliative method only to be followed?" and, upon the whole, he concludes against their extirpation, except in such as are of the scirrhus kind, in young healthy people, and have been occasioned by trauma or other external causes.

More modern experience, however, has afforded a very different result, and given ample encouragement to the early performance of an operation, and even to making an attempt to cut away the disease, in every instance, both of the local and ulcerated kind, when such a measure can be so executed, as not to leave a portion of the cancerous mischief behind.

Mr. Hall, in 1776, published some valuable remarks on the present subject. At that period, he had extirpated from different parts of the body eight or nine scirrhus cancers, which were all ulcerated, except four; and all the patients, except two, recovered of the operation. Of the first forty-five cases, only six proved cancerous; in three more the others broke out again in different parts; and, in a fifth, there was the reappearance of scirrhus tumors, at a distance from the original disease. These cancers, however, did not appear till three years after the operation; and the woman was carried off by a fever before they had made any progress. All the rest of the forty-five continued well as long as they lived; or, as he says, Mr. Hall, at this day. One of these survived the operation thirty years; and eleven were then

sized, although the last of them was cured in March, 1871.

If the next thirty-three, one lived only four months; and, in five more, the disease broke out afresh, after having been once healed. The reason why, out of forty-five cases, only four or five proved successful, and six, out of thirty-three, was as follows: "The extraordinary success I met with (says Mr. Hill) made numerous patients resort to me from all parts of the country, several of whom, after delaying till there was little probability of a cure, by exhaustion or any other means, forced me to perform the operation, contrary both to my judgment and inclination."

Upon a survey, in April, 1874, made with a view to publication, the readers about thirty. Total cured of different ages, from infancy downwards, sometimes; of whom there were then living thirty-nine. In twenty-eight of that number, the operation had been performed more than two years before; and, it shows, it had been done in the course of the last two years. So that, upon the whole, after thirty years' practice, thirty-nine of sixty-three patients, were alive and well, which gives Mr. Hill occasion to observe, that the different patients lived so long, after the extinction of the tumor, as, according to the bills of mortality, they would have done, had they never had any cancer, or undergone any operation.

The remaining twenty-five, which complete the eighty-two, were cured since the year 1795. Twenty-two of those had been cured at least two years; and some of them, it may be remarked, were severely, and one ninety years old.

In the year 1779, the size of the whole stood thus: Of eighty-eight cancers, extirpated at least five years before, not cured, two; broke out afresh, none; threatened with a relapse, one; in all, twelve, which is less than a seventh part of the whole number. At that time, there were about fifty patients alive and sound, whose cancers had been extirpated above two years before.

Mr. R. Bell, who was present at many of these cures, bears witness to Mr. Hill's accuracy; and the latter very judiciously states, that "from these and many other authenticated facts, which, if necessary, might be adduced of the success attending the extirpation of cancers, there is, it is presumed, very great reason for considering the disease, in general, as a local complaint, not originally connected with any disorder of the system." With respect to Mr. Bell's opinion, that a general anæmia must seldom, or perhaps never, occur, but in consequence of the cancerous virus being absorbed into the constitution from some local affection, much doubt attends even this supposition, though the practical inference from it is what cannot be fought with, viz. in every case of real cancer, or rather in such circumstances, as from their nature are known generally to terminate in cancer, we should have recourse to extirpation as early as possible; "and if this were done soon after the appearance of such affections, or before the formation of cancer taken place, their return would probably be a very rare occurrence."—(Synops. of Surgery, vol. 7.)

Mr. Astley Cooper admits, that the operation is followed by a return of the disease in many cases, the average number of which, however, he does not state, though he says that they do not amount to one-fourth.—(Lancet, vol. 2, p. 263.)

How often is the operation determined upon, because the apple is enlarged, and transverse thereby unaccommodated? Yet says Mr. Charles Bell, with reference to the cause of this change, as previously explained, "it is never clear, that if the apple is fully retracted, and if this has been evident for any considerable time, the operation has been too long deferred."—(Med. Chir. Trans. vol. 12, p. 221.)

Mr. Astley Cooper is adverse to the performance of the operation when symptoms are present; for he has known patients die in two or three days, who had been operated upon while laboring under that symptom. On examination after death, water was found in their stomach, and likewise in the pleura.—(Lancet, vol. 2, p. 263.)

The same experienced surgeon gives it as his opinion, that a breast should never be removed, unless the patient has undergone no course of alterative medicine, no Purgative pills and the subsequent abolition of menses, or (what he prefers) the extinction of ges-

tation with acids and rhubarb. Then the remission may be supposed, and the danger of a relapse diminished.—(Vol. cit. p. 270.)

After comparing the different accounts of cures given by Mease and Hill, well might Richard say: "*Non esse dicendum, de non-voluptatis morbo hæc esse loqui, debuisse fieri potest.*"—(Chir. Clin. Jan. 2.)

MEMBERS AND CLERGY WHOSE NAMES HAVE BEEN CALLED FOR THE FUND OF SCIENTIFIC ACQUISITION.

It is a concerned point, whether a truly cancerous disease is susceptible of any process, by which a spontaneous cure can be effected. It appears certain, however, that a violent inflammation, ending in suppuration, may sometimes accomplish an entire remission of a cancerous affection, and that the more advanced any then be. Facts, confirming this observation, are so occasionally exemplified in cases where cancer is met, and accidental inflammations have led to the same fortunate result, as we may be convinced of by examples recorded by Sir Edward Dimes, Bart., &c. The latter writer, observing to the effect which cancer sometimes yields to red itself of the disease by the inflammation and bursting of the tumor, takes the opportunity to relate the following case. A woman, aged forty-eight, of a strong constitution, was admitted into the Hospital of St. John, with a cancerous tumor of the right breast. The swelling, after becoming softer, and affected with fluctuating pain, was extracted with an incision, which extended to the skin of the part, and of the adjacent cellular membrane. The whole of the swelling burst, and was discharged. A lump, consisting of healthy appearance, remained after this kind of extraction, and lasted in two months.—(Venerable Chir. J. L. p. 263, vol. 2.)

In general, however, it must be confessed that inflammation renders things worse instead of better, and by converting local cancers into violent ones, increases the patient's death, or so all, every means to cure more difficult, and finally any attempts, which, on such a principle, might be made for relief.

Of the general remedies, tartaric, arsenic, opium, belladonna, &c. have been employed with some hope.

Orfila, on cancerous morbidities, gives his opinion on the spontaneous burst of cancer, which has been several times on S. According to him, some persons possess very evident powers over cancer, and has cured a great many cases; but in less regulated habits it has not been found successful; and even in some of the instances adduced by Baron Staudenfeld, it is evident, as he by no means proved that the disease was truly cancer. The public have very little to say in relation to this medicine, as a means of relieving cancer. Mr. J. Barnes declares, that in cancerous diseases, he never knew ketchup produce even temporary relief.—(See Comment.)

Belladonna was highly recommended by Lemery. During its use, he kept the bowels open with castor, administered every second day. The dose should be, at first, a grain of the dried leaves, fresh rubbed. The quantity may be gradually increased to that of four or five grains. The patient is best frequently attended, the dose being first one grain, and afterwards increased by degrees to five. The opinion of belladonna has not been supported by any limited success in cases of true cancer.

Brocton has often been tried in numerous cases, and was highly recommended by the ancients. Mr. J. Barnes says, he has employed it occasionally, without little effect. The constant dose, at first, is three grains of the extract.

Acetous has also been given. And it is a very powerful and dangerous remedy, a patient usually being with only half of a grain of the extract night and morning. Numerous physicians, Paris quacks, physicians, &c. have also been recommended, but they are less readily employed, which is a rational proof of their inefficiency. Mr. J. Barnes tried the 1800 extract of acetous, without any benefit. Barnes prescribed the ferrous sulphate, but without any decided success.

Digitalis becomes vascular system, and may act on both the absorbent, bleeding, &c. It has, however, no specific virtue in curing cancerous diseases.

Opium is seldom employed, with the exception of giving opium, although it is probably a safe and useful agent in cases of cancer, especially when there is much

more frequently used. For the purpose of lessening the pain of cancerous diseases, it is very freely prescribed.

Tonic sometimes improve the general health, but they never produce any specific effect on the local disease.

Ironmedals though arsenic a specific for cancers. Further experience has not, however, confirmed the truth of this opinion, though there are many practitioners who continue to think highly of the efficacy of the mineral in various forms of disease, which have sometimes been classed with cancer; and in many cases of leprosy, and malignant ulcers of the tongue and other parts, it may really produce greater claims to further trial than perhaps any other medicine yet suggested. It is unfortunately such a powerful astringent as to dry the face, lips, and tongue, and in some of the best remedies for leprosy. Mr. Hill observes: "Experience has furnished me with some substantial reasons for recommending arsenic as a medicine of considerable merit, both with regard to solid ulcers and scirrhus, which may one day terminate in that heathen species of ulcer; and although I cannot as yet say it will remove the one, or cure the other, yet certainly and surely as necessary (sometimes) does a separate swelling, or even cure, for it will, in a great majority of cases, retard the progress of the true scirrhus, to destroy, and often prevent its becoming cancer. In some, it has appeared to dissipate such swellings completely."—*Glasg. Med. and Surg. Journ.* vol. 4, p. 38.

Mercury, in conjunction with decoctions of ginseng, kava-kava, &c., has been recommended, but Mr. J. Burns remarks, as far as is now positively ascertained, that that mercury always counteracts the arsenic, especially when in the dissolved state. Plummer's pills and the other arsenical preparations of Dr. A. Cooper, as adjuvants to be given previously to an operation, with the design of lessening the chance of a return of the disease, have been already noticed.

Sulphate of copper also has been tried, but, in general, it retains no character as a remedy for cancer. The same may be said of married harys.

The carbonate of iron was particularly recommended by Mr. Combe. Besides the carbonate of iron, he sometimes prescribed the citrate of iron and potash, and the phosphate, oxyphosphate, and oxyphosphate of the metal. Some practitioners can bear these preparations only in small quantities; they affect most patients with constipation, and many with head-ache and dyspepsia. These circumstances, therefore, must be attended to in regulating the dose. The above preparations have seldom given less than thirty grains, in divided doses, in a day, or exceeded sixty. He prescribes the citrate of iron for internal use, and states, that it cures best in small doses frequently repeated. If chronic be treated with white of egg, have a little pure fixed alkali added, and then be made into pills with powdered lactative. Arsenic is recommended for the removal of warts. When a grain is troscured with a pill containing four grains of carbonate of iron, and taken thrice a day, the constitution will be divided. When the internal use of iron brings on hæmorrhoids, difficult menses, a quick, sometimes full pulse, which is not generally hard and wiry, excessive thirst, hæmorrhoids, &c., and such symptoms become distressing, the iron is to be left off, and four grains of calomel given every fifth day.

At the same time that preparations of iron were internally administered, Mr. Combe had employed externally, the carbonate of iron, the citrate, phosphate, oxyphosphate, and sulphate of iron, blended with water, in the form of a thick paste, which was applied once every third or four hours. To small cancers, the most continuous applied a solution of the sulphate of iron (1 to 8) or water. The solution of iron, diluted with eight of water in weight of water, was also used. The same was used on the part affected by means of diluted iron, 1 to 10, and mixed with a piece of lint with a piece of tape of the cloth.—*See Essay on the Effects of the Carbonate and other preparations of Iron in Cancer*, &c. 2d ed. New York, 1833.

Many remedies have inspired entirely in cases of cancer, because very hot and subacute diseases only supposed to be cancerous, have got well under their use. Such is probably the case with the carbonates of iron.

The only mode of treatment which Mr. Pearson has ever seen do any particular benefit in cancer, is that of keeping the patient on a diet highly nutritious for the support of life, such as barley-water alone, &c., &c. A milk diet has also been recommended.

Will respect to the effects of a very low diet, Mr. A. Cooper is strongly against the plan: if the patient be already weak, he says, you will then render her still weaker, and soon bring her to the grave; in proportion as the strength declines, the pulse is quickened. He further declares, that no power to medicine which has any specific power over the disease, though the state of the constitution may sometimes be improved by Plummer's pills given at bedtime, and the following draught daily. R. Infus. gentian, 15. Tinct. nuxvom. ʒi. Aconit. canth. gr. v. Spts. carbon. ʒss. Mucos. Ulmar. be also regarded as having no particular effect on scirrhus disease. Mr. A. Cooper only sanctions the use of steel trepanning when the disease is confined to the ducts. In such cases, he recommends the compound calomel pill at night, and the following draught twice a day. R. Vin. ferri ʒi. Aconit. canth. gr. vii. Aq. menth. M. ʒi. Tinct. canth. ʒi. ʒss. He also approves of anodynes for the relief of the suffering; as the first, and the lightest opiate, or the black drop, combined with the sugar pill, and a little of the opium extract. One of his patients derived much relief from the following pill. R. Tinct. stramon. gr. i. Camph. gr. i. M. R. pill. He lives in the country.—(*See Lancet*, vol. 2, p. 107.)

The old surgeons commonly dressed cancerous ulcers with arsenical applications. Venetian red ointment dipped in the juice of the solanum; while others employed a mixture with the oil of rose and preparations of lead and mercury. Others had recourse to the hyposulphate; but of late years leeches have been used, the famous iodo-calcic application; and in many cases, as Mr. J. Burns observes, they have undoubtedly checked pain and retarded fever; but this is all which can reasonably be expected. His thinks cancer patients better than those of leeches, as they possess a more active and more powerful system.

Dr. A. Cooper has no confidence in the utility of evaporating lotions. When applications are too extensive as ulcers, the dressing which he mostly prescribes, is a plaster, made by blending ʒi. of the extract of belladonna with ʒi. of soap ointment. When inflammation is present, he does not object to the use of leeches. All local applications, as well as internal medicines, he considers as merely palliatives, unassisted by any power of curing really scirrhus diseases.

The issue of cancers, having been thought to resemble that of the subluxation of joints (over of salivary), and the operation of the issue being the best agent for decomposing and destroying such swell, it has been recommended as an application to cancerous warts. It may correct the fever; but it will never accomplish a cure. Carbolic acid has been used not only to correct the fever, but in some instances, completely to cure the disease. It was long ago proposed, says Mr. J. Burns, by Ferrius, and was lately brought forward by Dr. Ewald. Experience, however, has not shown that the efficacy of carbolic acid, in cases of cancer, is very great. Ferrius remarks, "After the first application, the cancerous sore appears to become a more favorable aspect; the scales which drive from it become thicker, thicker, and purer, and the flesh has a redder and fresher color; but these flattering appearances are fleeting, for in they continue long, the necessarily returns to its former state, and its progress goes on as before the application." The best method of applying carbolic acid is by means of a shablon, the mouth of which is inserted round the sore with adhesive plaster. The air is introduced by a pipe inserted at the other end.

Sometimes the strongest positive is employed. Iodo-calcic, as a local application, is said to be almost as efficacious as iodo-calcic.

The constant gastric juice, absorbent powders, &c. have been tried, but without any evident good.—(*See J. Burns on Inflammation*, vol. 2.)

Mr. Pearson rejected all internal remedies, as ineffectual in the treatment of cancer, and, in the early stages of the complaint, recommended a method of practice founded on his idea of the inflammatory ex-

fall of the disease. "It is the beginning of serious affections of the breast and limbs, the mode I have adopted of treating every kind, is by incision repeatedly applied to the parts. In this course, however, I have often been interrupted by the rapid inflammation produced in some attacks around the parts where they finished. In these cases I have, I have often used a weak, below I must proceed to the suppuration of them. When the suppuration had not in support the temporary stops, in any of the tumors, in so as affected the circulation, either in, or even probably some well become cancerous, I had have recourse to general bleedings. But whether local or general, permanent for a sufficient length of time or temporary. During the whole course, including such practice, yet the patients have not suffered by repeated bleedings; on the contrary, when they passed a certain time without being cured, they felt a renewal of these symptoms, and of course even enjoyed, desired to be cured again. To this plan of repeated bleedings, I joined a milk and vegetable diet, avoiding wine, spirits, and fermented liquors." Mr. Ponsard used also to keep the belly open, and employ antispasmodic applications.

Of the method of treating cancer by pressure, I have spoken in another work (*First Lines of the Practice of Surgery*, vol. ii.) and therefore in this place I need barely remark, that it is a practice, which none of the best modern surgeons think entitled to approbation.

From the preceding account, we may infer that scarcely any relation is to be placed in any known remedy to plan in any cases of non-malignant, and elevated cancers. The operation is the only rational mode of getting rid of the disease; and to make time, so as to abate the disorder in order to a second degree, merely for the sake of trying various antispasmodic remedies, is conduct unworthy of a more skilful practitioner.

Potency, is early used, it may be right to medicinal of arsenic, various preparations of iron, those of iodoine, and, in general, of the extract of the hydriodate of potash, which Dr. Wagner found capable of dispersing any swelling reputed to be cancerous.—(*See Médec. Mod. June, 1816*.) In France, this extract is also applied to various tumors. Dr. Wagner's compound only eighteen grains of the hydriodate of potash to six drachms of lard, but in France the proportions are as much as two drachms of the first article to an ounce of the second. But the practitioner should beware of destroying too much due to medicines which will in all probability prove analogous to the object for which they are exhibited. Grise is also alleged to have succeeded in transmutation an absorption of the whole of the diseased breast, by applying an ointment, composed of ʒi. of hydriodate of potash, and ʒij. of lard. Mr. Hill, of Chester, has recorded one case, very favorable to the further trials of iodine. The cancer was in the unexcited state. He dressed it with an ointment consisting of ʒi. of the hydriodate to ʒij. of lard, and gave the patient internally thirty drops at a time of a solution of thirty-six grains of the hydriodate in six ounces of distilled water. The result was such astonishment of the disease, that a cure was confidently expected; but, in the end, the ulcer returned in former dimensions and malignant character.—(*See Méd. Mod. June, No. 87, p. 283*.) Upon the whole, the question is what we should generally adopt, as the error and the safest means of getting rid of cancerous diseases. As I have before mentioned, the operation is always indispensable, when every particle of the disease can be removed by it. Even large open ulcers, if they can be surgically cut away, are often capable of being effectively cured.

The removal of cancerous disorders, even in the slightest and most trivial cases, should always be effected with the scalpel, in preference to caustics; the use of which, though it may sometimes succeed by producing a complete destruction of the diseased parts, causes severe agony, and inflicts wounds in the yet existing cancerous and the diseased parts, often renders the cure more complicated, and kills the patients; and this is a very short space of time.

In cancerous tumors, the treatment generally considered as every application of the disease kind, together with the pain and inflammation which necessarily exists, are strong objections. Therefore the remedy, which is chiefly wanted, is equally indispensable. Not one can be more or less suitable except every case of cancerous tumor

with any matter, as just cut with the knife, be with this you immediately give an order respecting the surface surrounding the disease, so as to see and feel whether the diseased parts are completely removed, or whether any portion of the disease remains. With respect to the pain, that of caustics is infinitely greater than tolerable, and more tedious, than that removed by the knife. When caustics also take in destroying every particle of the disease at once, it almost always tends to enlarge, in a very rapid way, the original boundaries of the morbid. For as soon as the method of removing scabs and ulcerated cancers, as Messrs. Boissier & Co.

"There is, perhaps, no disease to which our minds are less," which has likewise faithful of symptoms, it has judged us prone a harvest of wealth and reputation to ignorant and unscrupulous charlatans in the case of cancer, and we give them the evils of amputation in the treatment of this disease, and so find have been the several caustic plasters which are exposed to the public, it is a matter of surprise that such impostors have not been made the subject for the indignation of the patients of our medical order.

Our nation has given us a third and judicious description of the various modifications of cancer, and as much well enable the young student easily to pass out his diagnosis. But his chief difficulty will be to convince his patient and friends that every cancerous tumor, whether limited, or extensive, or even malignant or epithelioid, local inflammation, is not a cancer. These dangerous cancer doctors who swear to cure a vast number, gain their reputation for success by promising all such local affections to be cured, and then applying their cancer-plaster until they have a sore surface which soon granulates and heals by curettement. The cure of cancer is then published, and thousands of certificates, under seals, are deluging the country, it being such cases in patients, many of whom sometimes are completely responsible of cancerous disease in any of its forms. Hence it is that we find many cases being cured in New-York by these impostors than there are cases of the genuine disease in the United States, according to a year that there are observed a cure. Within three years I have known more than a hundred instances of these impostures. Sometimes it takes a nerve material, or an extension by amputation, is treated by a cancer-plaster; and the most mentioned is, in a short time space, that he saw a child with scabs under the treatment of one of these impostors, who had already inserted a caustic plaster beneath the tumor by a caustic application. Very often an impostor goes, on the other side, an obscure theorist, has some airy notions, which had been already discussed in the matter as the worst kind of cancer, although neither possessed any specific character whatever.

All these impostures, however, are comparatively innocent; because, for the most part, they only inflict pain on the skin, and a wound on the pockets of those who become their victims. But they do not without lesser crimes; with their impostures their business-ventures, and they devote every method attached to the structure of the female breast to be a cancerous tumor, and predict the surgeon with his knife, and death in the rear, as the certain results of delay in using on this cancer and its roots. I have known many wives and mothers ruined for life by submitting to the experiments of ignorance and folly in matters of the particular structure, which required, for the most part, no medical attention. And in one instance I saw a poor old, the widowed mother of a number of children, of what is called aneurismal fever, produced by a plaster applied to the mamma, which if occasionally removed, would have existed for years, but which her friends, and her friends, and the wickedness of one of these impostors had changed into a malignant cancer. It was in perfect health when the cancer was applied, the scarlet turned blackish and deep; an unhealthy inflammation succeeded, involving the other breast and the mammary gland, soon which she was soon bedridden, and lingered eleven months, dying at the result of the disease. This is only one among a number of instances in which death has resulted in this city from cancerous tumors.

It will perhaps be expected that I should point, in the place, to the treatment of cancerous tumors by amputation, a remedy which some years since secured a cure

ludens are not infrequent, and when the disease is neglected, extreme sloughing sometimes happens.

Lying is a nearly constant, unvoluntary food, and sometimes to chillsiness, are supposed to be conducive to the disorder. Its course seems not to be unobscured, but it is remarked that the disease prevails most in houses where children are crowded together. The complaint is sometimes suspected to be contagious.

Though children are the usual subjects of it, grown up persons do not always escape its attacks.

The treatment consists in exciting diseased flesh and loose pieces of bone; directing a milk and vegetable diet, with a prudent quantity of sweetened liquors; and prescribing bark, sesquioxide, and cinch bark with sulphur acid.

The best external applications are, distilled rose-water; hyacinth; the doctored carboline, with sulphate of zinc; tincture of myrrh; lime-water, with spirit of wine, &c.—(See *Parsons's Principles of Surgery*, ed. 2, p. 357.)

CANTHA UIDES. Spanish or French fly, with which the common blistering plaster is made. In surgery they are also prescribed in incisions of ulcers, galls, &c. The thimble is sometimes added to strengthen blistering to increase their effect. When applied to the skin or taken into the stomach, they have a powerful tendency to act upon the urinary organs, and especially to irritate and inflame the neck of the bladder, and occasion suppuration. In children, these effects are particularly frequent.—(See *Blister*.)

Under the article *Tincture of Cantharides* will be found some practical remarks on the effects of this remedy in several diseases. I would therefore only remark in this place, although not strictly appertaining to surgery, that the internal exhibition of cantharides will be found to possess extraordinary efficacy as evacuating an habitual propensity to abortion, which the female constitution sometimes acquires. There is known this remedy succeed after almost successive abortions had occurred, notwithstanding all the efforts made to prevent its repetition. It is not should be considered as increasing ones tend strongly to induce, which result may be lessened by applying a dilute tincture of cantharides to a blistered surface.—(See *Cantharides*.)

CAPITULUM. (From *capitulum*, a woman's hat.) A beetle-headed ulcer, the middle of which is applied to the scrofula. After two or three under the redness increases, sometimes upon the forehead and vertex; then, one being reflected over the vertex, to the forehead, the other is continued in a circular track. They meet cross each other upon the forehead, after which the first head is turned back obliquely towards the neck, and reflected by the side of the neck. The last is continued in a circular direction, and the first is brought again over the neck, suture, backwards and forwards, and so continued till the whole head is covered. By the patients this kind of cure sometimes applied in case of hydrocephalus: it has no advantage, however, and is now hardly ever used.

CAPILLARY PNEUMIA. A very minute crack in the skull. The term here refers to its preventing the appearance of a hair.

CAPITRUM. See *Scrofula*.

CARRUNCLE. (From *carrus*, a turning wheel.) An ulcer. This is a very common symptom in the plague, but comes on also sometimes as a primary disease. The first symptoms are great heat and violent pain in some part of the body, on which some one or several excoriations, attended with great itching and a burning heat, follow, which a preternatural but very deep, and extremely hard tumour may be felt. In some respects it resembles the furuncle, but differs from it in having no central core, and in terminating in gangrene under the skin instead of suppurating.—(See *Cancer's Dictionary*, vol. 1, p. 30, *Plutarchus*, 122.) It soon assumes a dark red or purple colour about the centre, but is comparatively pale towards the edges. A better frequently appears on the spot, which, as it increases an intolerable itching, is often scratched by the patient. The tumor being then broken, a brown mucus is discharged, and an excruciating appearance. Many vesicles of the kind are sometimes produced upon one limb.—(See *Med. Lib. vol. 1*.)

Furuncles have been distinguished into the benign and malignant kinds, but as far as the disease can be

judged of at present in this country, the distinction is only decided upon the different degrees of violence with which it makes its attack. Some carcinoma are said to be pestilential, while others are not at all contagious. Periodically, all cases run with this kind are of the last sort; for no opportunities of remarking the pestilential anthers have occurred in England since the fatal periods of 1603 and 1604.

The carcinoma sometimes appears in persons affected with typhoid fever, in which case it is attended with great weight and stiffness of the adjacent parts; the patient is restless and pale, the tongue white, and a deep red, and much; the pulse late, often sometimes pulse, sometimes very faint, with all the other symptoms, in an exaggerated degree, which attend typhoid fever. The patient often complains much of his head, either from pain or giddiness. Sometimes he is delirious; at other times he cannot get the least sleep. Sometimes he is delirious. The case is also apt to be attended with chilliness of figure, and profuse sweats. The patient is sometimes twenty, sometimes affected with a profusion of mucus; he generally complains of loss of appetite, nausea, and vomiting, takes little nourishment, complains of difficulty of breathing, and is extremely low with prostration of the heart, and sometimes lividity.—(See *Amplified Out*, vol. 2, p. 122.)

Sometimes a little slough, of a black colour, issues from the middle of the tumour. This was supposed by the ancients to be a sign of the body toward a cure or hard cure, by the violence of the disease. In some instances, the carcinoma is considered as a sort of gangrenous affection of the cellular membrane.—(See *Cantharides*.) The progress of carcinoma in the puerperal state is generally quick. They run in various; they have been known to be as large as a pail. Considerable local pain and tenderness always attend the disease. The skin, indeed, has a peculiar feel, like that of ivory. As the complaint advances, several operations gradually form in the tumour. Though these openings there is discharged a greenish, bloody fluid, irritable matter. The tumour swelling it often very extensive, even when no sign of suppuration can be externally discovered.

The carcinoma is often so low and talented, that death follows. The carcinoma, indeed, is most frequent in old persons, whose constitutions have been injured by voracious living; and again an opinion is expressed that the local disease, derived by the general disorder of the system, should very often receive a diaphanous aspect.

The degree of pain may generally be estimated by the largeness and situation of the tumour, the number of more swellings at the same time, the age of the patient, and the state of the constitution.

With regard to the local treatment, the great thing is to make an early and free incision into the tumour, so as to allow the sloughs and matter to escape. This, with the view of facilitating the course of the discharge and internal sloughs of the cellular membrane, it is a good plan to remove, with a pair of scissors, a part of the dead skin, as soon as its detachment is sufficiently advanced.—(See *Amplified Out*, vol. 2, p. 141.)

As much of the contents as possible is to be removed, and, and then the part is to be exposed to a constant position. Indeed, until the cancer is opened, no application is more proper than constant pressure, and when an incision has been made, the part is preferably to be exposed to a constant position, made with bark, tincture of iron, &c., or some other made with the sulphates of copper and zinc, nitrate of silver, &c. Incisions are also often made, but both before and after an opening has been made. As the discharge is exceedingly fatal and dangerous, it is to be removed by a fresh position of the part. The use of the cautery is to be considered till all the sloughs have separated, and the surface of the cavity appears red, and in a granulating way, when and let and a plaster of some coagulating matter should be applied, together with a compress and bandage. The incision is to be made in the line of the cancer, in which the disease is to be carried on by making a proper opening in the line of every protrusion, and if any part is to be removed, a frequent removal of the dead portions of carcinoma cases. Mr. Blandin finally declares

surface of the diseased bone, and extends from the slightest caries; while in the soft parts a want generally leads down to the caries, and creates a very firm, dark-colored surface. These symptoms, however, as well as the tendency in the accompanying short or stunted to produce large fungous granulations, are more common in cases of caries than in those of cancer, some of which may remain a very long time without uniting with any external sore, although, as shown in the illustration in the cancer produced by various diseases of the joints. And, indeed, particular forms of caries (if they deserve that name) are rarely accompanied with suppuration: a fact to which I shall again advert.

The absorption of bone, like that of soft parts (says Dr. Thomson), may be distinguished into constitutional, progressive, and obliterative. We have ample proof of the constitutional absorption, or that which is salutary, healthy, and necessarily taking place from every part of the substance of bone, in the deposition and removal of phosphate of lime, that has been tinged with ossification. If too much earth be absorbed, the quantity of animal matter will be relatively increased, and a disposition given to softness of the bones—a state which exists in the bones of children in the disease called the rickets, and in the bones of older people in that denominated ossification ossea, or the rickets of grown people.

I have already had occasion to mention the effects of the progressive absorption of bone, as manifested in the progress of aneurysms and other tumors, to the skin; but the formation of pus is by no means a necessary, constant, or even frequent attendant on the progressive absorption of bone. Hydatids in the frame of sheep, various growing from the pia or dura mater in the human body (see *Nature History*), or abscesses seated over the cranium, or within the cavity of the chest, are often the cause of the whole substance of a bone being removed, layer after layer, by progressive absorption, without the formation of a single particle of pus. (See *Anatomy*.) This state of the bone has often been confounded, but improperly, with that state of the bone which arises from obliterative absorption, the state which is properly denominated caries, and in which one or more sections of continuity may be produced upon the surface, or in the substance of the bone. The abscesses occurring in bones by the venereal disease, afford by far the best marked examples of the effects and appearances of obliterative absorption, or cancer in bones. &c.—(See *Thomson's Lectures on Inflammation*, p. 294.)

Caries has been divided into three kinds, according to the nature of its causes: 1. Caries from external causes; 2. From an internal local cause, where no outward injury of the bone, and no external constitutional disease can be supposed to have produced the disorder, and where the affection can be removed by local means. The caries of the finger-bones from whitlow is regarded as a specimen of this form of the disease. Perhaps, however, the case is generally rather an instance of necrosis. 3. From a general internal cause, or constitutional disease, in which case, besides local symptoms, it is necessary to employ such medicines as are calculated to obviate the particular affection of the system, whence the diseased state of the bone has originated.

But, in addition to these general divisions of the subject, there are many considerations in relation to the nature of caries which may be said yet to be in obscurity. If, as a modern writer remarks, the symptoms of the bones, the nature of their organization, and the structure of their diseases would be an attentive observer trace the formation, development, and progress of caries, no doubt there would be noticed a diversity in its symptoms corresponding to its different species; and probably it would be found that a venereal or syphilitic cause would vary in its origin and progress as much from a poison arising from a purely local cause, as a venereal or syphilitic fever differs from the kind of affection that follows a common abscess. (See *Dr. Sydenham's Med. & S. p. 24*.) The cancerous caries, as it has been termed, which permeates the whole substance of a bone, and gives it an appearance as if it had been bored in hundreds of places, is a very different affection from some other forms of the disease, whether superficial or extending to the deeper trunks of the bone.

Mr. Sydenham regards the distinction of caries into the

dry, moist, cancerous, &c. only as the result of the confusion of caries with other morbid states of the osseous tissue. The dry is in reality necrosis, as already noticed. A cancerous bone, after amputation, according to Mr. Sydenham, looks as if it had been bored; being fissured, white, and more brittle than normal, and is very attended with pain or less excruciating, so as to expose the cellular structure. It usually contains a greenish liquid matter, which has been partially dissolved by the necessary immersion in hot water. (See *Edin. Med. and Surg. Journ.* vol. 36, p. 257.)

Abscesses situated in the vicinity of bones are frequently thought to be the cause both of necrosis and caries. This was the ancient doctrine, and it has many various advocates in modern times, especially Mr. Lisfranc. (See *Edin. Med. and Surg. Journ.* vol. 26, p. 241.) Hence, the rule to open such abscesses at an early period, in order to prevent the bone from being affected, if near abscesses, like those which form over the inferior surface of the tibia and tibiotal process of the temporal bone, is frequently attended with great injury or necrosis, the latter is mostly the cause and not the effect of the suppuration. But, which is a third instance, moderns think, never mistake the end and the means which it is in contact until the question is changed by exposure to the air. When an abscess forms in the osseous part of the process of the abdomen, the peritoneum of that part, internally, thus becomes, instead of being destroyed, because thick and strong enough to resist the extension of the abscess towards the cavity of the abdomen. So also when an abscess is formed over a bone, not irregularly drained or hurt by the same causes which produced the abscess, and not injured by being kept exposed, or by frequent excoriation, applications, either cause necrosis is likely to happen. On the contrary, the peritoneum, like the peritoneum, becomes thickened, and the abscesses are formed over it. In the opinion of Mr. Sydenham, cancerous, like necrosis, is induced directly by the effect of violence. If depends, he says, upon a peculiar morbid action, which is probably in all cases produced by inflammation. "Many people think that pressure, such as that of an aneurysm, causes absorption of bone, and gives rise to an appearance which might be mistaken for cancer by an inexperienced or careless observer, but would never for a moment suppose that any one acquainted with the distinctive characters of the disease. The surface exposed by simple absorption differs in no respect from that which would have appeared if the excavation had been effected by violence. We do not here perceive the hardness, whitening, and brittleness of cancer; neither is there any matter secreted from it; and as soon as the cancer is removed the disease ceases. The effect of pressure is retarding absorption, without inducing cancer, it will soon in these contact cases of aneurysms where internal exfoliation occurs, and the confined pus enters a way for its escape, show the sides of these passages, as produced, the disease as they are called, as it is respect various, or until the healthy action. The usual collection of matter tends to be evacuated by the relief the patient from pain, or prevent swelling of the fluid, but no absorption will be continued of caries being produced by its pressure." (See *Sydenham's Med. & S. p. 258*.)

But though this gentleman thinks that inflammation generally, if not always, produces caries, he recognizes this consequence as not invariably following inflammation of even suppuration. "In cases of compound fracture, suppuration, mortification of parts, &c. we then say we have suppuration and gangrene in the most satisfactory manner. We observe the same thing occasionally in joints, which become ankylosed with being the seat of abscesses." At the same time, Mr. Sydenham believes that suppuration of bone, which either takes place spontaneously, or as consequence of slight external injury, is very frequently followed by caries, much more so than when it results from a vessel which does not lead to the bone tissues.

Mr. Sydenham says that caries seldom affects the bone to a great depth. "There are often not an articulating extremely carious order as when internal necrosis, and even to the center. At other times we find it hollowed out into a cavity, the surface of which is carious, while the internal shell is sound. The very limited extent of the disease often continues remarkably with the extreme obliquity and severity of the symp-

ness. This there is in my possession a right-hand which I took from the body of a woman who had suffered under caries of the tracheal major for thirty-two years; yet the whole disease may be covered by the point of a finger, and is not thicker than a cocoon."—(*Gynec. et Gyn. Med. Jour.*, v. 31, p. 227.)

The vascular disease is sometimes a cause of caries; sometimes of necrosis; frequently of both affections together, and in other instances of necrosis. When it attacks the bones of the nose, its destructive effects arise partly from necrosis, and partly from caries, and the former is fully developed. The bones of the palate are sometimes affected in the same manner, but on a very occasional effect upon them is clearly necrosis.

In cases of cancer of the alveolar the alveolar and the bone sometimes become carious. I believe that in such cases the disease of the bone has nothing to do with the cancer; it is to be regarded as an extension. It is a mere effect of the original disease; and if the cancerous bone could be removed together with every particle of the disease of the soft parts, a cure would probably follow. On supposing the cancer bone would the only portion of the disease left, it is reasonable that the cancer might yet still be cured. At the same time it is proper to remember what has been mentioned in the article Cancer, that Dr. J. C. Cooper refers to his Lectures on some bones taken from cancerous subjects, whose the alveolar substance is deposited in their structure.

Under the article Trachea I have stated a very remarkable case of caries from syphilis occurring in the trachea, together with its successful treatment. The celebrated Richman of Paris, has several times reported various cases, and this operation has since been repeated by Dr. McCallum, of Philadelphia, and by Dr. Hildworth, of Virginia.—*Revue.*

Caries arising from syphilis more commonly affects the ribs, cranium, nose, ear, and maxilla, and maxilla; and I believe is mostly accompanied with a greater or less degree of necrosis.

Caries of the vertebrae is known by peculiar symptoms, among which a paralysis of the inferior extremities (lower limbs) are the most remarkable.

Caries parietis, caries from an external or local external cause is less dangerous than that which proceeds from a constitutional disease, particularly when the latter is difficult of cure.

Caries of the spongy part of the bones is more difficult to cure than a similar affection of the compact part. Caries of the nasal and frontal bones is particularly obstinate. These bones being in close contact, the disease cannot easily be prevented from spreading from one to the other. An operation is often the only means of cure. The disease is frequently the cause when the spongy heads of the long bones forming the large limbs become carious. Even this mode of relief is not reasonable when the head of the bone has very deeply, like that of the os femoris.

Caries of the ossa cranialis that observed to be particularly difficult of cure.

Caries from scabies, the most frequent cause of all the examples of this disease of the bones (Wismann), is more difficult of cure than that from syphilis and scabies; for some efficacious remedies against the latter diseases are known; but scabies cannot be said to be within the reach of medicine. The prognosis is less favourable in old than young subjects, and much depends on the extent of the disease, the patient's strength, and the state of the soft parts.

When caries arises from constitutional disease, internal remedies are of course indicated. Then mercurials and other in medicine put a stop to caries from syphilis; while vegetable and acids cure both the scabby and the caries dependent on it.

According to various indications in the treatment of caries, it is fitted to produce a change in the action of the diseased portion of bone, whereby it may regain a healthy state, or destroy it altogether.

In the case of constitutional caries, the first object seems to be brought about by the operation of such remedies as remove the original disease; and I should not doubt whether, in these cases, any very active local treatment is necessary or free from objection. Of course, this remedy is suited to apply only to caries in which no sound bone, necrosis or plan, which is known to be a seriously case remedy for the general disease. This is not the case in cancerous, scabious, and necrotic, caries, trachea, trachea, trachea, and

local disease, are extensively symptomatic.—(*New Journal and Physician*.) But surgeons have proceeded farther, and not content with issues, blisters, emulsions, &c. as means for quieting the action of the diseased bone, they have constantly recommended applying directly upon it the strongest stimulants, as the tincture of alcohol or opium, a solution of the acetate of nitrate, concentrated vinegar, or diluted nitric acid.

For the destruction of caries, the actual and powerful caustics and cutting instruments have been employed.

On the contrary, and particularly in France, the plan of touching carious parts of bones with the actual cautery, after bringing them fairly into view by the process of the knife, is still pursued. It is thought that the burning iron acts by changing the caries into a necrosis, isolating the diseased sound parts, and causing the action of the vessels, by which the dead or diseased part of the bone would be thrown off. Such is the doctrine (taught by Boyer, and such is the practice) sanctioned by some surgeons of the present day, among whom I find Mr. Lisson.

Mr. Hey succeeded in cutting away a carious part of the tibia. He began the operation by dissecting off the projections of flesh which had arisen from the bone, and then carried on, by means of a circular-headed saw, a wedge of the tibia two inches in length. The removal of this portion brought into view a caries of the cancelli almost as extensive as the piece already removed. With different trephines, suited to the breadth of the caries, Mr. Hey removed the diseased cancelli of the bone quite through to the opposite lamella. As the caries extended in various directions, it was not possible to remove the whole of it with a trephine without removing a large portion of the sound part of the bone, which Mr. Hey wished to avoid. By the assistance, therefore, of a strong sharp-pointed knife, he pursued the caries in every direction, until every part was taken away which had an unsteady appearance. The wound was simply dressed with dry cal, the whole surface was speedily swathed with good granulations, and a complete cure was obtained without any exhibition.

Mr. Hey concludes this subject as follows: "I have treated some other cases of caries of the tibia in the same manner, and with equal success. Where the extent of the caries is not so great as to prevent a complete removal of the diseased part, this mode, it is extremely useful, and far superior to the use of the potential or actual cautery.

The trephine as the wanted where the cancelli of the bone are not affected with the caries. The diseased parts of the lamella may be removed with gouges or small chisels. Granulations of flesh will then arise from the sound parts of the bone, and become united with the integuments, which ought to be preserved as far as is possible."—(*Pract. Obs. on Surgery*.)

Mr. Hey also regards osseous as the best method of destroying carious bone, since he says "more can be done by the saw, or cutting plane, in a few seconds, than by the actual cautery in as many weeks or months," and he strongly objects to the application of the cautery to the bone after the extension of the caries part.—(*Gynec. et Gyn. Jour.*, v. 31, p. 226.) In this point, every judicious surgeon must, I think, agree with him.

Dr. Nuss, surgeon to the Northern Infirmary of Liverpool, has lately published the result of his experience in caries; and he finds that, when extensive is not possible, the most useful efficient treatment consists in applying nitrate of silver to the carious part, and exhibiting the compound decoction of marsh-mallows.—(*New Jour. Med. and Surg. Jour.*, No. 94.)

In the treatment of caries, particularly of that form of it which accompanies white swellings, Mr. Lisson considers blisters and caustics as equally to be productive of much good. In the first or inflammatory stage, he prescribes topical bleeding, followed with moderate, and followed by issues, scarification, blisters, or the medicinal purgative. However, he thinks the most efficient remedy is the nitrate. "In all diseased parts of the joints," says Mr. Lisson, "this remedy affords the most speedy and complete relief, at the expense but of a trifling part of no long duration. The pain does not appear to be greater than that arising from the irritation of an eschar by issues, or any other of the potential caustics, such as lead and during the same

as may be lost when the eye is in various positions. 2. The opacity is somewhat concave. 3. Its contour inclines rather to a pyramid or saddle than to a gray. 4. The degree of the opacity is not at all in a ratio to the degree of opacity; the patient being almost blind. 5. The pupil is more or less dilated; the iris nearly or quite motionless, its pupillary edge being more and there flaring out at night, and otherwise it is somewhat peculiar. 6. Eyes the contrast itself is so pale so faint and transparent in the natural state. 7. The temporary increase or diminution of blindness, sometimes in patients with interstitial keratitis, tends, depends, as it does with interstitial, upon the degree of dilatation of the pupil or the degree of light, but upon causes which need either to depress or excite the system. 8. The opacity which is in the vitreous body, permits persons around the object of a candle, to see a white which is not, but has all the hue of the vitreous; indeed, the flame itself presents these colors, and when the patient goes to some distance from it, it becomes somewhat. 9. At no period of the complaint are operations of any service in enabling the patient to see better. Blind objects are not situated to one side or the other, but are equally seen from those which are distant from the eye. (See *Rees's Lectures on the Eye*, p. 293, 294.) 10. The sight is not temporarily improved by the application of belladonna. (See *Rees's Lectures on the Eye*, p. 293.)

According to this author, the first and most important division of cataract, is into the *senile* and *juvenile*. For the senile is usually, situated in the posterior chamber, between the vitreous humor and lens, and is usually termed a cataract, may be either within the lens of the capsule of the lens, or between the anterior layer of that capsule and the iris. The first case is the senile, the second the juvenile cataract.

A juvenile cataract, when a primary disease, and attended from the first with other mental effects in the eye, is usually a single independent affection, on the contrary, as the senile cataract is generally the consequence of injured epithelium, it is almost always more or less attended with a partial opacity of the anterior layer of the capsule, and, at times, with a genuine cataract.

The first variety of juvenile cataract noticed by Rees is this, which he calls *leucocoria*; it always begins in the centre or very nucleus of the lens, usually presenting a dark, yellowish gray color, which is somewhat deeper at the centre than at the margin of the pupil; a chamber is established even when the disease is in its third complete stage. The leucocoria cataract is always formed very slowly, and, except when the iris is too thick-colored, it is more or less attended with a blackish stain at the edge of the pupil, which may become glaucous as the disease advances. A genuine leucocoria cataract never extends up to the iris or the expansion or contraction of the iris; but does it often in its highest degree deprive the patient of all power of vision, when, in early stages, or when the pupil is beautifully dilated with hyoscine or belladonna, is often capable of distinguishing pretty well many objects which are placed laterally with respect to the eye. A leucocoria cataract is usually, at some distance from the eye, so that the extent of the posterior chamber is manifest, when the opacity presents more or less of a pitted appearance, and never that of very white, dense spots. Frequently, as Rees observes, the leucocoria cataract is associated with any change in the capsule, or the liquor of Morgagni. In most cases of senile cataract, not attended by inflammation, the capsule is said to become transparent. (See *Rees's Lectures on the Diseases of the Eye*, p. 293, 294, 295.)

The second species of juvenile cataract noticed by Rees is *the senile*, which he thinks should also be called *senile*, as the expansion is equal to the eye. The disease seldom commences in the centre of the lens, but usually arises at the margin of the lens of the iris, very white, shining points, streaks, or spots, its color, sometimes, is always very light, and never altogether invisible, even when the disease is completely formed. The dotted or mottled appearance of this cataract is also particularly noticed by Mr. Travers. (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) The blackish ring which, when the iris is light-colored, is more or less evident in this than the leucocoria cataract, is here seen being to the shadow of the iris, but to its dark border; for this cataract is too near the iris for any sta-

low to be formed. This senile cataract, however, is somewhat at variance with what Mr. Travers has observed; he thinks a transparent interposition can be seen as dilating the pupil with belladonna, in his recent case of the capsule cataract; and he believes that the black ring may be confined to the capsule, and not the margin of the capsule. But when the opacity of the lens is different, this sign of capsule cataract. (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) The disease also has some effect on the thickness of the iris, at least in its early stages. A capsule cataract, several authors have the duty of stating, is followed by dilation of the lens itself; a fact, says Rees, which, except surgery, no other means can remedy; it is through the medium of the capsule, that the particles of the lens are incessantly undergoing the changes of renewal and reproduction.

The capsule cataract is subdivided by Rees into the anterior capsule cataract, the posterior capsule cataract, and the capsular cataract, in which both the front and back portions of the membrane are opaque.

The anterior capsule cataract, which is met at all stages, does not extend as long as the lens after it has attained a high degree, but, according to Rees, is more common with an opacity, and, according to Mr. Travers, without any opacity of the lens itself. (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) When the capsule is completely opaque (says Mr. Travers), we can hardly judge of the nature of the lens. But in such examples, "the lens is constantly distinguished in bulk; it undergoes a considerable amount of the opacity, so as to present of itself a brownish translucent cataract. The consequence of the opacity is the dilatation of the vessels of the capsule, from which more of the lens are derived. When the capsule opacity is congested, it is either partly, or wholly, or only a very small piece of lens remains. When the opacity is complete (says Rees), the lens is some greatly reduced in bulk, as appears from the falling in or concavity of the iris, which loses its support, and is demonstrated in the operation. This observation renders the operation with the needle applicable to the cataract in which the capsule is opaque, in cases which are not very recent." (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) In the anterior capsule cataract, according to Mr. Travers, the lens does not generally undergo dilatation, but, for the most part, is enlarged, in consequence of becoming opaque and soft. But he admits, that the process is frequently the case is always, only a small portion of the lens being left, and the rest of the contents of the capsule fluid. (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) The anterior capsule cataract may be known by its light gray and, in some places, completely chalk-white color, observed by staring, another of point the stroke and spots. As the capsule is at the same time the lens is not, the posterior chamber is increased, and the cataract is not infrequently close to the iris, especially when the lens has also completely lost its transparency. In this stage, the membranes of the iris are become rendered less thick, and the shadow at the margin of the pupil is entirely absent. Hence, vision is not only lost, but quite impaired, is termed to my patient's sensation of light, whether the patient be in a light or shady situation; and frequently a kind light is completely insensible to him.

The posterior capsule cataract belongs to the more dense of the disease of the eye; but, says Rees, when it happens, the lens always perforates in the center much more quickly than when in the anterior capsule cataract. Hence the disease is never observed up to the perfect development. Respecting the state of the lens, some difference prevails between the statements of Rees and those of Mr. Travers: the latter gentleman informs us, that when the opacity of the posterior capsule is with which he agrees with Rees in considering as very rare, the lens and anterior capsule are usually transparent; "and when this is not the case, and the cataract except with a posterior side of opaque capsule, it is always accompanied with a considerable dilatation of the lens." (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) And in speaking of the opacity of the posterior capsule, in another work, he informs us, that he has not observed that, in this case, the lens undergoes any dilatation. (See *Rees's Lectures on the Diseases of the Eye*, p. 293.) Like the anterior capsule cataract, it is denoted by a white-gray, or chalk-white color; but no light-colored, chalk-white spots and streaks are ever discernible, which, while the lens re-

time its transparency, may be owing to the distance of the camera from the page. However, the equality noticed behind the page always seems certain when the eye is inspected, not from before, but from every side of it. While the posterior wall of the organ is not absolutely opaque, the retina is practically affected, the strength is only more or less modified, and sometimes, possibly with the aid of a compensating glass, a tolerable degree of vision is enjoyed, notwithstanding the considerable opacity behind the pupil. This system of occlusion has not, of course any influence over the actions of the eye and after the lens becomes opaque, it is not obscured.

Though the complete negative answer is not the final opinion of present ophthalmists, it is rather worth to be very cautious. In relation to the symptoms of the anterior pupillary cataract, it presents few, few factors of characters which indicate it is obviously an interesting; viz. the iris is nearly transparent, the catarrhal conjunctiva is not so thickened, the posterior chamber of the globe is not so filled; and an incipient cataract might really surprise the apprehension of the oculists were object to the fact, unless he obtained them at the contrary by producing an artificial cataract of the pupil with hyaline or corneal clouds. But, though the iris seems more transparent, by the large extent, towards the center it is convex, being and the pupil cut away perceive the strongest kinds of light. Though such is the statement of these, I cannot with Mr. Griffin to the regarding the more darkness, which may attract my large soft cataract, as well as the complete cataract, as, so as to make a consideration of the extension of the latter.—*Operative Surgery of the Eye*, p. 253.

The third species of posterior cataract is the *cataracta Morgagniana*, which sometimes forms a capsule and sometimes coalesces with the posterior cataract. It resembles the rayed form of the cataract, or, more, perhaps, that Mr. Travers regards the same as a partly applied film (*Synonymus of Diseases of the Eye*, 204). The following is the form of cataract described by Morgagni the same; it proceeds from a shallow excavation of the lens into a silky fluid, or thin jelly, frequently attended with a complete capsule cataract. Its origin is said to be always quick, and an immediate effect of chemical action on the eye. The following are the symptoms of the case, while it is unaccompanied with cataract of the broad capsule; a state which can never persist long. Though the colour is dark, white is a delicate amber, the most of diluted milk. The white pupil seems cloudy, but whenever the eyelid moves suddenly and violently, or the eyelid is rubbed over the eye, the opaque substance changed their shape and position. The posterior chamber is mostly unaltered; which may be owing to the quantity of fluid or aqueous substance collected. While the lens and capsule are not essentially changed, the vision suffers only a diminution, though it is very rapid, and small objects cannot be distinguished at all.

When, however, the lens and capsule become opaque, vision is "quite extinct," a certain power of seeing the light being, however, only remaining. Not infrequently, says Herr, when the lens itself is in a clouded state, the capsule is partially opaque, the eye is kept quiet for a few minutes, and the patient stands or sits in an upright posture, two rows of opaque matter can be plainly seen, the upper being the thin white of the two; the lower presenting a darker whitening. Moreover, as soon as the patient suddenly or violently moves his eye or head, or the eyelid is raised over the eye, both these rows of opaque matter disappear, and the cause of the opacity toward the pupil again, are restored.

The fourth species of garden chamber described by Bosc, is the *oxygonolobus* chamber, to which he conceives the figure of Monopson in an altered state may likewise often occur, as may be inferred from the prodigious size of this chamber. It is by no means uncommon, and is attended with the following symptomatic systems. The extent of the cavity, close to the ureter, is partly chalc-walls, partly one that of chalc-walls, and in many places both these cavities may be evidently seen disposed one over the other, thus of chalc-walls, however, being always most superficial. The portion of the eye to the most of light merely causes very motion of the eye, but the pupil is circular, without any angles in it. After the application of the section of laminae or of laminae, the two chambers again expand slowly, and the pupil is long in returning to its

former diameter. Besides the obliteration of the greater diameter, the opening now itself is heavily dilated, in consequence of the true being pushed forward the coccyx by the very large size of the tumour, and hence the protrusion of tube is very common.

The capsule-hypertrophic cataract is not infrequently the consequence of a slow inflammatory process in the iris, the lens, and its capsule; and known several varieties of this case, and an even superficial consideration of a squamous cataract; all which different modifications, says Kels, should be correctly understood previously to an operation, in order to take a just opinion of its nature, and to know what method of operating ought to be adopted.

An opaque vesicle that first in the capsule between cataract, composed with slight depression of the vitreous body, an anterior capsule of the lens. These often degeneration upon the front layer of the capsule, as they only there, put on very different appearances, and occasionally involve various modifications. For instance, the vesicle is sometimes in the cataract, when the vitreous body is formed substances upon the anterior layer of its capsule are so arranged as to resemble the variegated appearance of marble. The vesicle is yellow superficially, cataract, when the vitreous substances move each other, leaving darker-colored inclosures. The vitreous capsule-hypertrophic cataract, when the vitreous matter runs in concentric strata, forming the tubular of eye pupil. The central capsule-hypertrophic cataract, when a single elevated, white, vitreous point is formed on the anterior of capsule, while the rest of the membrane is tolerably clear, and the lens not sufficiently opaque. The striated capsule-hypertrophic cataract, when the front layer of the capsule presents several features resembling depression on its surface. Vitreous cataract, or posterior capsule-hypertrophic cataract, when one-half of the front layer of the vitreous body, mixed with a vitreous pupa. In all these, and some other changes, says Kels, the lens is found to be converted to its very viscous into a crystalline or milky substance.

The second variety of the *Cephus-littoralis* cannot be distinguished by Herr, as the *verrucosus*, indicated by its gray-white color; sometimes lying on stones in the water so as to push the iris forwards towards the apex, and at other times appearing to be at a distance from the iris. These immaturities, by Herr, possibly should always depend upon the position of the body, directed towards and from the water, the vapour, marine animals, globular form, and projects considerably towards the anterior chamber. Frequently, this variety of the *Cephus-littoralis* catenates the head in such a manner the uppermost translucent or shining, and sometimes opacifying, use applied. According to Herr, the extent of such undulations in the catenae is wrong to the broken in very slight contraction of the capsule of the lens with the neighbouring tissues. The same surface has never seen any one of this kind, which had not been preceded by a violent expansion of the outer subjunctive part of the lens. Both layers of the capsule are opaque, and sometimes considerably thickened. The third variety of the *Cephus-littoralis* catenae described by Herr, as the pyramidal or conical, which is one of the rarer types of the *Cephus*, and always brought on by violent intense inflammation of the eye, especially of having the lens, the capsule, and the iris. It may be known by a white, almost shining, opaque, narrow the projecting, new-formed substance, which grows from the centre of the anterior layer of the capsule, and is always in close contact with the pupillary margin of the iris. Hence the iris is always quite immovable and the pupil irregular. Sometimes this growth from the capsule extends itself so far into the anterior chamber, as nearly to touch the inner surface of the cornea, and sometimes actually to adhere firmly to it; a circumstance, says Herr, which is very unusual from casual rubbing of the cornea, though not dissimilar to the lypemias in perforated. The power of admitting light is feeble and imperfect, and sometimes entirely abolished. Mr. Gualini (see I lately) very correctly regards this case as an advanced degree of the disease previously described under the name given by Herr, of (*Opaculatus*). It might, indeed, be mistaken as a species; *catenae*.—(See Gualini's *Opaculatus* in the *Ann. d. Med.*).

The formal variety of the supralaryngeal contact is the salient one. Though principally associated with a vowel

lence chamber, but blended with purities of purulent matter, so as to give it a light-yellowish tinge and a clouded appearance. The pupil is always diminished, adherent to the corneal surface, and smaller; the reticulations fine projects towards the cornea; and not only the strength, but even the perception of light, is completely lost, or the latter at least much diminished.

A rare variety of squamous cataract, described by Beer, is the blood-*cataract*. It arises from some considerable injury of the eye, a large quantity of blood is extravasated in the chambers, and slowly absorbed during the opacification caused by the violence, a part of it, however, remaining in the posterior chamber, in the form of small clots crystallized in the lymph, which was effused during the inflammation; or else in the centre of a more indurated and perfected case of hydrops. Blood is effused in the chambers of the eye, and not mixing with the fluid, still continues in the vessels behind the pupil, after the matter has been absorbed. In the first example, this cataract resembles a reddish web, interwoven with silvery streaks, or flowers; the pupil, though singular, is seldom obliterated; the iris mostly of pale pinkness; and not seldom is the light cherry-colored, but a partial degree of vision sometimes retained. The cataract, in the second instance, the opacity behind the pupil is very dense, white, streaked with reddish or brownish points or spots, having a branched appearance, and frequently projecting through the pupil into the anterior chamber; while the peripheral is very small and singular, the iris quite insensible to motion, and constantly under no perception of light rays, or only a very limited indistinct vision of it. Beer says that this cataract may easily be mistaken for glaucoma, and that an albugo can only be made out with a good magnifying glass.

The double cataract of Schmidt, the *schismatic cataract* of Richter, or the *partial cataract*, as Beer observes, is not one of the most frequent of the squamous cataracts, and is certainly the consequence of a violent compression of the globe of the eye, with or without a wound, whereby a portion of the capsule of the eye is torn, and becomes placed upon the vitreous layer of the capsule, more or less resembling its appearance the schismatic form of the stone formed in dentine. Immediately after such a compression of the eyeball, the patient complains of a serious dimness and confusion of vision. Whoever examines the eye soon superficially, will certainly not discern the poem of the laceration lying upon the eye perfectly immovable crystals of the lens, for the first careful inspection will be necessary for the purpose, and consequent the aid of a magnifying glass will be requisite. But as the lens and capsule are movable at the same time loosened from their connections, they likewise generally become deprived of their transparency, and as soon as this has happened, the displaced portion of the capsule can be readily seen. When inflammation ensues, the flakes of the capsule become closely adherent to the first layer of the capsule of the lens, and even the papillary edge of the capsule acquires the same kind of denseness, so that the perception of light is diminished. But says Beer, when inflammation follows, the papillary margin of the lens remains free, the lens perfectly movable, the light easily distinguishable, though the lens and capsule be entirely opaque, and sometimes the flakes of the capsule resembling the schismatic streaks of the dentine either in shape, size, and position, but never completely detached though they may not connect with in the capsule. (Lectures on the Eye, p. 263, 264.)

A particular case is described by Mr. Guthrie, as more light denoting the name of *choroid cataract*; a young, healthy person of constitution of the eye, in consequence of a few or gradual inflammation of the eye. The pupil shows merely a point, which remains sufficiently free from opacity for light to take place with the aid of spectacles. "On the redness of the inflammation, the iris, by the natural efforts of the part, or under the influence of treatment, is drawn towards the outer circle or circumference, and the pupil is apparently enlarged; but the vision, in consequence, does not improve with its anterior part, or seems affected in the capsule of the lens on considerable portion of its periphery so to prevent the passage of the rays of light through it, while the pupil, as a distance,

seems to be of its natural size and blackness." A minute inspection, however, shows that the pupil is nearly closed. Mr. Guthrie adds, that the operation for closed pupil, by division (the only proper one), is not advisable as long as the patient can see well enough for the common purposes of life. (New Operative Surgery of the Eye, p. 264.)

Another classification of cataracts, which is of great importance to an operator, is that which is founded upon their consistence; for as their consistence, the nature not only a great difference in the common treatment, but also in the choice of a method of operation.

When the opacity (as is often more extended than in the natural state, we require a considerable degree of firmness, the case is termed a *firm or hard cataract*. When the consistence of the lens seems to be softened into a watery or other kind of fluid, being in the eye, the case is considered usually as *fluid cataract*. When the opacity (as is in a softening consistency) has been fluid, but about as consistent as a thick jelly or mucus, the case is termed a *soft or mucus cataract*. When the anterior or posterior layer of the crystalline capsule becomes opaque, after the lens itself has been removed from this eye, the cataract is termed a *posterior cataract*.

The *lenticular cataract*, the *lenticular* and smaller becomes, in this case, the *lenticular* part of the eye, as well as the *lenticular*, or a *lenticular* appearing according to Beer, is *very dark*. The consistence between the cataract and pupil, sometimes, is *firmly* distinct, sometimes *less* from opacity, and, when the pupil is closed, can even place per se, the *lenticular* part. In the *fluid* state of the pupil, a *black* circle surrounding the lens is very perceptible. The *regions* of the eye are the *anterior* and the *posterior* surface of the cataract appears to, without any degree of opacity. (Lectures on the Eye, p. 277, 278. See, also, p. 279, 280.)

Beer says, that it is only the positive lenticular cataract which can be hard, and it is clearly not with it that, *lenticular* persons; but, with regard to the *lenticular*, that all cataracts in old persons are *firm*, and this is frequently confirmed by experience. In cataracts confined from this, and *lenticular*, the lens is sometimes *hard* divided, as hard as wood, such of a *lenticular* grows, color, and with fewest surfaces as far as if they had been compressed. This cataract sometimes has depressed the *lenticular* cataract, and is very difficult to take out completely in an operation, being liable to be mistaken for an *lenticular* cataract. Hence, in order to prevent it entirely, the pupil should always be dilated with *lenticular* or *lenticular*.

To the *lenticular* cataract, Beer refers several *lenticular* cataracts, namely, the *lenticular* and *lenticular*, or *lenticular* cataracts, that in which helps the *lenticular* or *lenticular*, the *lenticular* cataract in particular, and the *lenticular* cataract, which has *lenticular* partly *lenticular*, as well as all the varieties of *lenticular* cataract. (Lectures on the Eye, p. 280.)

The *lenticular* cataract has usually a *lenticular*, and *lenticular* spots and streaks, diffuse in color from the rest of the cataract, sometimes observable on it. These are *lenticular* and *lenticular* and *lenticular*, when frequent and diffuse masses of the *lenticular* or when the eye is *lenticular* and *lenticular*, sometimes also these spots and streaks are *lenticular* and *lenticular*. The lower portion of the *lenticular* cataract is *lenticular* than the upper, probably because the *lenticular* and *lenticular* part of the *lenticular* had not descended to the bottom of the capsule.

The *lenticular* lens, as it leaves the *lenticular*, *lenticular* acquires an *lenticular* size. Hence, the *lenticular* is *lenticular*, and the *lenticular* cataract is *lenticular*. Sometimes, the *lenticular* cataract is *lenticular* between the *lenticular* and *lenticular* of the pupil. In *lenticular* cataracts, this opacity is usually very much *lenticular*, and the *lenticular* moves slowly and *lenticular*. This opacity (because we cannot see the *lenticular* and *lenticular* cataract). The *lenticular* cataract is sometimes of such a *lenticular*, that it prevents the *lenticular* and *lenticular* part of the *lenticular* to be *lenticular* it assumes a *lenticular* appearance. Patients who have *lenticular* cataracts, generally *lenticular* light from *lenticular* very *lenticular*, and sometimes *lenticular* at all; partly, because the cataract, when it is *lenticular*, lies so close to the iris, that few, or no rays

cases preventing the formation of cataracts in the approach of age; also, and lower than strong fires, as furnaces and stoves, in glass-blowing, &c. To England, little credence given to these opinions.

But says, that he has also noticed the occasional observation, that exposing the eye to the action of concentrated acids, sulphuric and nitric, and sometimes better as a cataract; a substance which will be recorded in this account with some illustration, when the vapour of ether has been occasionally recommended for the dispersion of opacities of the lens and its capsule. The dose of ether is now supposed to be confined to the aqueous, vitreous body, and to be dropped among the vitreous in drops and drops. Mr. Keen, says, I remember that the cataract has mostly been the result of inflammation.

Whether of the eye, where the aqueous has poured the capsule and the lens, and especially violent inflammation of the capsule of the globe or of the eye, though no record may exist, are in general followed by a cataract of an extensive character. This is the case, says Keen, even when an inflammation arises from the injury, the cataract often occurring in a few hours, and on an exceedingly a degree as to admit of being removed.

The cause of cataract thus rapidly produced must depend, in every opinion upon the complete separation of the lens from its connection with the capsule, and not necessarily in part upon the denudation of the capsule itself from the neighbouring textures, for in both cases the membrane also gradually becomes opaque.

According to Keen, cataracts frequently arise from a slow, insidious inflammation of the capsule and capsule.

With respect to the progress, it must be evident from what has been proved, that there are many cataracts in which the cure is highly problematical, and often in which the responsibility of restoring vision, even to the slightest degree, may be produced with absolute certainty.

With the above positive information which surgeons possess concerning the origin of cataracts, scarcely any operations can ever be undertaken of curing opacity of the lens, and its capsule, by means of resolution, so as to separate all division for its operation. A possibility of success, as Keen remarks, can exist only when the cause of the cataract is superficial, and of complete removal, and the disease is in an early stage. And he has observed from several and repeated trials, that the attempt to cure an incipient opacity will never succeed, except when some other, and various general or local action of a curable nature has been a chief cause in the production of the opacity of the eye; as, for instance, scrofula, in a mild form, syphilis, &c. and the sudden cure of venereal, or old ulcers of the legs, &c. is a slow tedious inflammation of the iris and capsule of the lens. In some examples of this kind, Keen could only check the further progress of the opacity, and even when the opacity was improved, it was never rendered perfectly clear. And when the opacity was so far advanced and quite developed, with the exception of the general improvement of the health, and an improved state of eye, whereby it was put in a better condition for the operation, but the slightest benefit was deemed too uncertain. (Keen, &c. p. 122.)

In this country the best is put in force, between opposing the constitutional influence of inflammation, and scrofula, syphilis, &c. in the production of cataracts, except when with general causes directly cause inflammation of the eye, and opacity of the lens, or its capsule is brought on as a consequence of such inflammation. Indeed, Mr. Keen mistakes that scrofula inflammation is rarely produced by the action of the eye, and that syphilis seldom is not more subject to vulgar than other individuals, an opinion in which I perfectly coincide. He also remarks, that there is an evidence of syphilis, patients being particularly liable to cataracts, and this even when they have suffered severely and frequently. It seems to me, however, because the proof of this and other constitutional diseases is to respect the formation of an opacity of the lens and its capsule, and the inflammation of the eye is caused by these (see therefore *History of the Eye*, p. 241), a statement which I think is altogether to every fact, required to be so daily corrected.

The principal external causes that have been tried for the cure of the cataract are, leeching, cupping, scarification, vesication, blisters, and leeches, and the chief internal remedies are opium, castor, nuxvom, calomel, mercury, and mercurials. Formerly, preparations of opium, calomel, and mercury, leeches, and blisters were violently extolled as specific for the disease.

Scrofula asserts that he checked the progress of a cataract by applying to the eye the oil of a pine, mixed with sugar; and Scrofula himself of having successfully tried for this purpose the oil of the yew-tree (see *History of the Eye*).

Calomel and leech have been used in various patients with a cure of cataract. Probably, however, many such cases might have been more operative if the system, or, at least, only transiently operative if the capsule, or disposition of the capsule posteriorly, the consequences of existing or previous inflammation. Whether played to remove the disease, as the power of any remedy to dissolve a cataract, and so to be and removed this tendency in various instances, he has confirmed by declaring that internal remedies, either of the venereal or any other kind, are inadvisable in the cure of this disease; and equally so, whether the opacity be in the capsule or in the vitreous, whether incipient or advanced.

Although the late Mr. Ware coincided with Keen and Keen is agreed by the uncertainty of all causes in the capsule, or even to prevent the progress of such opacity when open to light, yet, according to his observations, many cases prove that the powers of nature are often sufficient to accomplish these purposes. The opacity, in particular, which is produced by external causes, Mr. Ware had frequently seen dissipated in a short space of time, when no other part of the eye had been hurt. In such cases the crystalline lens is generally absorbed, or is removed by the body which is absorbed from very recent glasses. In some of these cases, though the crystalline lens has dissolved, the greater part of the capsule remained opaque, and the light was transmitted to the retina only through a small aperture which had become transparent in its centre. Instances are also recorded, in which cataracts formed within the vitreous, have been suddenly dissolved in consequence of an accidental blow to the eye. The remedies which Mr. Ware found more efficient than others, were the application to the eye itself of one or two drops of ether once or twice in the course of the day, and occasionally rubbing the eye over the lid with the point of the finger, first moistened with a weak solution of myristic liniment. While Mr. Keen admits that opium, percolation behind the eye have been cured under a course of medicine, he considers such cures very rare, and to have been accomplished only when the opacity arose from such disposition in the capsule, the result of sympathetic inflammation rather than from any affection of the crystalline itself. A business of the opacity, caused by the extension of inflammation of the iris to it, he says, may almost always be removed under the treatment proper for the cure of iris; but he does not believe that an opacity of the lens, distinctly dissolved like such, has ever been removed by medicine. He expresses his decided opinion, that if any leucular cataracts have really been cured, they were cured by external violence, and disappeared in consequence of their absorption in the aqueous humor, and direction of the vitreous, the opacity of the lens having been the result of a rupture of its capsule. Mr. Ware, who in the case proposed that the best cataracts might be cured by systematic application, and particularly the posterior eye, lately discovered this opinion; and it would seem from a note in the third edition of his book on the cataract, that the power has published in the first and second, and so proceeding from an external injury, since of the late description. (History of the Eye, p. 241.) At about the same time, a note is inserted as the only means affecting any rational hope of restoring the sight of persons afflicted with cataracts.

Notwithstanding also the prohibition to touch the operation, with all its different modifications, it really benefits, improvement will not always result in vision; say, says Keen, it is frequently accompanied; and even as inevitable since the power of the

retina. Richter and Wenzel make mention of these peculiarities, and the latter refers the phenomenon to the eye deriving its nerves wholly from the lamelliform ganglia, which are immediate signs of sight in considered entirely by another distinct nerve. Hence, the loss of the eye is not an adequate criterion, as authors have argued (Waller), that the retina is endowed with sensibility. Relating to this subject, Mr. Jones has made a curious remark; we attended, in conjunction with Hry and Jones, five children of a clergyman at London, near Boverly, who were all born blind. The voices, "Sweet dreams and luminous light from darkness, and although the pupil is, in darkness, whether the sense itself be connected, and has perhaps, yet these do not seem to depend upon the blind cannot be any wonder."—*Med. Obs. and Inq. vol. 6.*

The reciprocal sympathy between the two organs of sight is so strong, that as one, patients in various other physiological or pathological knowledge regarding them, sight, for a moment, is brought. Hence, in the examination of cataracts, a test of the highest importance is, keep one eye closely occluded from the light, while the surgeon is examining the state of the eye in the other; for the luminosity of the eye of light upon one eye, sensible in this cataract, is known to be the evidence in various extraordinary cases of the eye in the instance any attempt in the state of perfect darkness. In some instances of cataract, the pupil may be quite contracted, and yet sight, although somewhat, the performance of an operation.—*Wenzel.* There are two circumstances, however, which may prevent us from ascertaining whether the retina is sensible in light or not: the first is, a similar affection of the crystalline lens to the eye. Here Richter thought this circumstance might be formed of the nature of the case by observing the changes between the cataract and pupil; inferring that when the eye is between the pupil and cataract was accommodation, such an affection had intervened, and when the cataract did not seem particularly close to the pupil, and yet the pupil could not diminish light from darkness, that it was contracted with accommodation. The second circumstance, sometimes entirely preventing the success of any light, is the healthy retina, is the pupil, every form of the cataract.

But although the power of distinguishing light from darkness is more satisfactory than vision of the lens, it is not an unambiguous test of the retina being perfectly free from disease. While the cataract is in the process, the patient can yet distinguish light and the existence of cataract. Distortion of the pupil is also a doubtful criterion of the complication of cataract with the cataract. When the cataract is large, it is affected by the lens, the pupil is frequently much dilated, though the optic nerve may be normal and sound; the pupil often contains quite undisturbed a perfect cataract serum.—*(Richter.)*

From all this it must be inferred, 1st, That the irregularity and inconsistency of the symptoms of cataract serum, together with the possibility of partial states of the cataract rendering the patient utterly unconscious of the existence of light, make it necessary for the surgeon to be particularly attentive to the appearance and to the history of the original progress of the disease, as well as to understand the real condition of cataract serum. 2dly, That when the patient can distinguish light from darkness, though the eye may be motionless, there is good ground for trying an operation. Possibly in this circumstance an almost unerring rule might be found; but the phrase of the defect of the lens arising from other causes; the certainty that the optic body may be removed from the cataract of light (even if the sense of the cataract be removed, eye sight can be restored), and the impossibility that an operation to cure the cataract will render the other eye sight at all less susceptible of a cataract attempt. Frequently, the patient has a fully-formed cataract in one eye, which prevents the signs of accommodation, while an injured cataract, or even a cataract detached, exists in the other, which at present is free from some symptoms: In this case (says Mr. Travers), the cataract of the latter should be removed without delay.—*(Syncope, vol. 6, p. 214.)*

The conventional testimony of almost all writers upon the subject tends to prove, that the restoration of sight has sometimes been effected in the most hopeless cases; and I am therefore of opinion with Mr. Jones, that in

all doubtful cases an operation should be tried as a remedy by no means violent or hazardous.—*Med. Obs. and Inq. vol. 6, p. 227.*

I shall conclude this part of the subject with extracting the sentiment of Mr. Travers, viz. that it would be incorrect to say that the operation is unnecessary in all cases of cataract in which the patient has no sense of light; for it is possible that the density of the lens may be such as absolutely to exclude the light, and that the nature of the iris may be therefore preserved; or from some degree of firmness of the lens or adhesion of the iris to the capsule, that the pupil may be normal, and the appearance of the iris perfectly normal. But, undoubtedly, says Mr. Travers, a sense of the cataract is indispensable. "A strong sense of light by which he used to know the direction in which it enters the cataract, is a sensible of the falling of the eye, and of a globe, as the latter for eye, sense, corresponding to such a corresponding freedom of motion of the pupil, is a most favourable sign for the operation."—*(Synopsis of the Diseases of the Eye, p. 215.)*

As it is not infrequently happens that cataracts produced by external violence spontaneously disappear (*Part. Med. vol. 1*) the operation should not be too hastily recommended for them.

Regarding the question, whether an operation ought to be done when only one eye is affected with cataract, and the other is sound, some difference of opinion generally exists.

One reason assigned by the adherents of this principle, viz. that one eye is sufficient for the sustentation of life, is but of a physical description; and another, that the patient should never be able to see distinctly after the operation, by reason of the difference of the focus in the eyes, is a third ground for believing only a gradual improvement, inconsiderably transmitted from one eye to another. In support of this third last advanced, and to prove that cataract does sometimes, probably in general (if for other causes of failure exist), attend the practice of removing and extracting, when only one eye is affected with a cataract, I refer to a case reported by M. de la Motte.—*(Treatise de Maladies du Œil, 1^{re} Part, 1741, 12mo. Obs. sur une Cataracte, p. 180.)*

Barth Wenzel was the habit of extracting cataracts with the least successful result, when only one eye was affected with the disease, as may be learnt by referring to the cases here specified.—*Cases, 8, 13, 16, 17, 18, 20, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, 65, 66, 67, 68, 69, 70, 71, 72, 73, 74, 75, 76, 77, 78, 79, 80, 81, 82, 83, 84, 85, 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100.*

Richter was warmly convinced, that the advice not to operate when there is a cataract only in one eye, ought, for several reasons, to be disregarded: he reminds us of the wonderful consent between the eyes, so that one is seldom damaged without the other, sooner or later, falling into the same state; and hence he questions whether it may not be possible to prevent the loss of the sound eye, by a timely operation? An aim cannot point further distant with respect to cataract and cataract surgery.—*(Obs. Clin. June, 1741.)* He refers to the remarkable case related by St. Yves where a man was wounded in the right eye by a small shot, and shortly afterward had a cataract in it; he then gradually became blind in the left, but soon recovered his sight in it, after the cataract had been extracted from the right eye. Three let us notice, that St. Yves (*Medicine des Vues, chap. 13, art. 2*) makes no mention of any confusion in vision, in consequence of the different refracting powers of the two eyes in question. From several such publications, indeed, it would appear, that, in a few instances, an artificial cataract in one eye has actually disappeared of itself, after the operation had been performed by a surgeon on the other.—*(Recueil, in Med. and Physical Journ. vol. 12; and Mémoires de l'Acad. des Sciences, 1750, No. 27, p. 221.)* This is a circumstance which is urged by the latter physicians, not only as a strong reason for dispensing the cataract operation, that a cataract should never be operated upon while the other eye enjoys mental strength, but as a powerful testimony that the operation even in many cases so that if there been cataract in the other eye, the operation may be the means of preventing its formation, or if it be already beginning, the chance of its removal by the effect of the removal of the other cataract may be taken. In the *Medical and Physical Journ. de May,*

1838 is also an ingenious paper, defending the practice of operating upon only one eye as sufficient. Another reason, judiciously suggested by HENRY (Edin. Chirurgical Journal, &c.), for encouraging the above proposal, is, that in waiting until a cataract forms in the other eye, the existing one, which is at that age, perhaps, in the most favourable state for the operation, may undergo change so much for the worse (for instance, it may contract such adhesions to the iris) as either to destroy all prospect of relief, or even, afford but a very precarious and discouraging one. The length of time necessary to wait is also uncertain and various. I have seen a case in Mr. HENSLAND'S Hospital, who had had a cataract in one eye fifteen years; during all which time the other contained phlegm, and another case of twenty years' standing has lately been communicated to me. It is right to say, that HENSLAND lately suggested a contrary opinion to remove the cataract, yet without specifying the particular state which induced him to revoke his former sentiments. The principal reason stated by him is, that the patient op. only does not see much more actively with the two eyes, after the operation, than with one before it, but he frequently sees more confusedly, because the eye that has been operated on cannot so well sustain the aid of a glass, which perhaps the sound eye does not require. (Edinburgh Review for November, Driller, &c., p. 184.)

When I remember that our eyes are supplied by this system to contract the muscularity of the former cataract, when I also reflect upon the facts recorded by MILLER, JARVIS, and WARD, I return to my former opinion that Catarrh is necessary, as the noble ground of the advising the contrary opinion, that all our simple instances of this disorder have been accompanied, without questioning from what immediate cause the failure grows, there appears to me much reason to believe that the advice not to operate when there is only one cataract, and the otherwise to operate, so at least a subject which merits further investigation. WARD'S opinion is similar to that expressed by HENSLAND; he writes, "the eye from which the crystalline lens is removed cannot be restored to a degree of perfection at all equal to that of the sound eye, without the assistance of a convex glass" (Description of the Human Eye, and its Diseases, p. 82); but is not the person who uses both eyes at the same time, even with the improvement of being accustomed to employ a glass for the purpose, preferable to being blind of one? The objection stated at all events, proves that confusion in vision is not always the result of the cataract; whereas the fact is inconsistent with the general theory of vision in entirely sounder considerations. If it should be shown impossible to do it, we must enter that our knowledge of optics is insufficiently accurate; not less with well-ascertained examples, as stated above, as answers to it, brief.

When there is a fully formed cataract in one eye, and vision is retained in the other, the Traverser thinks the postponement of the operation wrong. "I am satisfied (says he) that the cataract eye, if it becomes the subject of an accidental inflammation, is strongly disposed to go into an abscess; and, besides, that the same does its utmost by the permanent employment of light. I speak from repeated observation of the fact. The objection to the operation on the ground of inconvenience, arising from the difference of force of the two eyes, when one only is the subject of disease, is trivial, and a consideration altogether unimportant; and a defect may always be remedied by glasses properly adjusted. In several cases of cataract coming upon a cataract, I have been disposed to regard the cataract as constituting and valuable of the lens as productive of a defective inflexion; in others, of a partial absorption of the vitreous humour." (Synopsis of Diseases of the Eye, p. 212.)

For some desired reason (see on the foregoing interesting question, I have referred to above), but he cannot not to have entered into the consideration at all. The only reason in which he appears to be wrong is, when he supposes the power of covering the eye, which yet possesses more of the vision when the other alone has a cataract than it does for the operation. (Edinburgh Review for November, Driller, &c., p. 213.)

There is one which has induced me to write so much upon the consideration of the question, whether an operation should be performed when only one eye

is affected, is a conviction of the importance of the decision under such a case. Were I to judge early when what has been said by writers, I should be inclined that a determination in the negative must be erroneous; but when I know that my experienced and judicious friend Mr. LAWSON joins in the belief that the practice is not productive of advantage, the only inference which I venture to make is, that the subject deserves further examination.

Mr. GUTHRIE says further, that if had not seen several cases in which great inconvenience was incurred from the confusion of vision caused by a successful operation, I add to his opinion, the reason is, that a slight degree of double vision does not last for a short time after the lens has been extracted. In those where the lens was broken up, however, the visual imperfection did not occur, as before the lens was absorbed, the eye became accustomed to imperfections. "The following cases (he) were the means I made up the cases in which attention was bestowed. Three were objects double when the double was first removed, and for nearly twenty days after, and then single. Two saw double for about two hours; and one of them, two days afterwards, was being surprised, and appeared his double vision, as perceived for a few seconds the same imperfection. A third saw constantly double for two days, and after that as frequently as ever he did; and the other three cases, as above mentioned, always single." (Edin. Med. and Surgical Journal, No. 24, p. 14.) On the whole, I consider this question, which is a very important one in practice, to be more difficultly settled, as far as the evidence of various writers can be extended, I think those who are in favour of operating upon a cataract, though the other eye is sound, see the best of the argument.

When there are cataracts in both eyes, most writers are of opinion that there is no reason why one should not be operated upon immediately after the other. As however, the operations are likely to be more common, perhaps partial, which both eyes are operated upon at the same time, it is given the preference in the hands, disapproves of this mode of proceeding, and states that in patients with cataracts in both eyes, his experience has taught him, that it is by no means advantageous to operate upon the cataract immediately after the other, but that it is better to wait until the eye is well, before any attempt is made upon the other. (Synopsis of Diseases of the Eye, p. 225.)

On this point, the following is HENRY'S sentiment: "When cataracts are completely formed in both eyes, the patient waiting, and every thing possible is to be done, both eyes may be operated upon at the same time. On the contrary, when any inflammation present, which renders the extent of the operation very doubtful, it is most desirable to make the attempt on one eye, even though the patient ultimately may have to be done, so that if the same operation should fail, but the completion of this cataract, afterward change consequently in the advantage of the patient, one eye would still be left for a second more favourable attempt." (Edinburgh Review for November, Driller, &c., p. 214.)

With regard to the question, I should say, with Mr. GUTHRIE, that if I were the patient myself, I should always prefer to have the operation done only on one eye at a distant distance. Some years ago, it was the opinion of several, that an operation should be performed when a cataract became the patient and attended the agent of double vision, and in a great of more substantially surgical, than can be made of the magnitude of such surgery, but when it is further considered, both essential light is to the improvement of sight, and the fourth is to the improvement of the independence of the patient. After when the cataract is steadily fixed, the double vision of being employed; that with the aid of an instrument, the vision can most efficiently be improved; that when the operation is delayed, the patient may arrive at a

Worse: that persons have not only had interests and passions deposited in books, at a very early age, even with the assistance of a operations table, have even had them extended (see Warre's note, p. 16, of *Worrell's treatise*), which is universally acknowledged to be a far more difficult process; and that the pupil of the eye is a young subject, is nearly as large as at an adult (*Warre's Description of the Human Eye, and its Diseases*, p. 34). I constantly thinking, with Mr. Latham, that after a child is old enough to hear an operation, the subject is only a contract with the gods; it may be proper at my age. Surgeons do not refuse to operate for the first time, as early as two years of age, to grow old; they do not wait for debility and poverty to the patient, to make him infirm, and considered the propriety of submitting quietly to the performance of the operation; they prescribe invariable orders, and give they nearly succeed in making, perhaps with uncertainty, that reliance upon the future state of very human being would afford, a very poor reliance, such as the nature of the operation demands; and why should they refuse to attempt the cure of cataracts in children, when the motives are more urgent, and it is equally in the power of art to subvert, and it is equally as effective as history and reason in the great nature? What experienced operators would first do those children, when the motives are more urgent, even on the most cautious and firm mind? (Quoted Reflections by the Author, 1813).

Unfortunately, the operation of eugenics has been mostly confined to the subject of operating on the children of criminals, and the propriety of the operation seems to be very strongly based on the basis of experience. It is even mentioned that it is possible that it may be successfully employed on children of the normal class. The Dr. Mr. Mendelsohn, *speaker* in the London Academy for eugenics, discussed the subject, and he said to himself that the principal object in promoting the adoption of this important improvement. His practice continued to be successful long ago, and he said, and the judgment, to be made, and with which, which is operated on the basis of eugenics, as well as those of eugenics, were followed by a degree of success which had never been previously witnessed, and which, indeed, was a new step in the most interesting branch of eugenics. Subjects from eugenics would be four years old, and would be made in from Mr. Mendelsohn's operations; and if any individuals from eugenics, Dr. Mendelsohn said, of this conference's population, is to be considered, the age of two years. "The public have been stimulated a degree of eugenics which would be the approach to eugenics with greater promise than at any earlier period; yet the eugenics has not been so rapid and steady as it does at a later period, after the eugenics has been more fully established."

But this is not the ground, although a considerable advantage of actually observing; for, in cases in which the points have no resemblance of external objects, the possible nature, such as a character habit of action. Through this, do a very long time after the thought has been formed by an organism, no necessary effort can be made to transfer the notion, nor direct the eye to objects with sufficient precision for the purpose of contrast and self-revision. Therefore, led by a later observation of the structure of an animal body, for want of being examined, follow as possible. Its similarity, in many of the more parts of the ages of four years and higher, could not be suggested in children, who had enjoyed vision from birth; but at eight years, or even earlier, the same was evidently not active, if indeed it was still there; and, from the age of fifteen and upwards, it was generally very rapidly and sometimes the mere perception of light removed. But these observations do not apply to those compound observations in which only one contrast of the two, and equally in space, the two experiences being consequent; for in these the being as experienced by a person, although an imperfect one, at extreme objects, the nature of the contrast which gives the place are essential, and the absorption of the acts does not take place. Therefore, in this variety of the division, the argument in favor of the self-observation is set on a much weaker or a novel one—it is preferable for the purpose of observation and experiment."

Proceedings of the Synopses of the East, 1857, 1858.

Benjamin Franklin, *Autobiography*, 1791, 100.

Before his death, strongly recommended the use of the needle in the free spinal treatment of infants and children. His mode of operating is fully hereafter given. The late Mr. Grooms, of Manchester, likewise acted the propriety of seeking young subjects, and died on the care of a rheumatic as preferable to that of ten years. "When, or, otherwise, things may have been taken against the safe and effectual use of the roasting-needle in infants, have always appeared to me weighty, and so easily transmissible, that without inquiring particularly into the real state of the question, I have long concluded that the same motives which would induce an operator to couch a patient at any period of infancy, would equally lead him to perform that operation at any subsequent time, when a cancer existed. Acting upon this persuasion, I have operated upon children of all ages for the same pain."—*Chin. Edw. Med. and Surgical Journal*, vol. 7, p. 203.

Mr. Gibson's paper being dated June, 1911, we would care to point out, however, that he passed this position from the year 1900, and he asserts that his experience had embraced a considerable number of years.

"In performing the operation of castrating infants, it has always appeared to me (superstitious gentleman), that the advantage to be gained by removing those so-called organs of passion, was so far from being down any obstacle which may occasionally be opposed to the education of the mind, that the risk of deranging the figure of the pupil, when so able a physician as its surgeon, had any doubts to be removed by mistakes and good management. Should even a slight change in its figure be produced, it is seldom in the least detrimental to distinct vision, and was scarcely to be considered a blemish in the eye of any one; except perhaps in that of a pro- stitute, who may easily accustom to himself the presence of an oval opening, where one of a constant form should exist. It may further be observed, that if an operation which depend upon his management of the eye, or so to consider it wisely by the instruction of the teaching-master, he can still himself of the assistance of a specialist to restrain its influence.

The following observations will apply principally to infants under thirty months old. The advantage which an operative procedure is offering upon a child of this age, as compared with a child of three years old, is speedier recovery. An infant is not conscious of the operation itself, and is free from the fears evoked by imagination, and can receive very facile assistance to stay awake employed as soon as it will admit. At thirty, age it has not acquired the power of entraining the eye deep in the socket, so that the operator has always a good prospect of introducing the needle promptly with ease by catching a proper opportunity. The eye has not in this time acquired the ordinary reflex power which, after a few years, is an obstacle just remarkable in children born blind, as evidenced just made even after birth. So that this impediment to every introduction of the needle does not exist in infants a few months old. The operator also has it as a good point to administer a dose of chloroform before the eye is necessary to expose the eye along with the operation has passed. With respect to the eye, if the eye itself is not generally that of the ordinary, it is more favorable for the operation than at a later period of life. As infants, the cornea is generally flat, and merely receives the first rupture of its containing capsule, which is in that case generally simple. The capsule, however, is tense and well preserved by the fluids, so as to form an aperture sufficiently large for the admission of light. The solid part which escapes from the capsule is soon removed by absorption. If, on the other hand, say Mr. Gibber's or external would be milk, it is generally of so juicy a nature that the few fragments of the posterior part of the capsule, and the fragments advanced of the capsule beneath, form the nearly continuous, and complete, without the necessity of a second opening, should the internal happen to be hard, there would be some difficulty in determining it was an eye.

[illegible]

placed, whereby the position, which is extremely inconvenient to the operator, may be immediately rectified. The subject should also be always supported in a steady position, so that a sufficient light may fall obliquely upon the eye, without any rays being reflected to the cornea, and becoming a hindrance to the operator. Nor should light ever be allowed to fall upon the eye. The surgeon stood at the head of the patient, whose head ought to be always supported by the operator's hand, whereby the latter will be enabled to see those parts, with the greatest convenience, every thing in the eye during the operation, and will not be under the necessity of raising the head too considerably. Supposing it to be the left eye which is to be operated upon, the patient is directed to draw down the lower eyelid with his left fore-finger, the end of which index is placed over the margin of the eyelid, against the globe of the eye. The middle finger is then to be applied at a distance very near the cornea, to the eyelid. The method now taken in the right hand the same instrument for the operation, viz. the pencil or knife, which is to be held like a pen, between the thumb and the fore and middle fingers. By this judicious arrangement of the fingers of the assistant and operator, which, indeed, is necessary, the distance between the fingers of the eye is very narrow, and the eyelids are brought close and work in the most, the smallest eye of an adult patient is able; for a point of the finger is disposed so every way, so that the eye can possibly turn away from the instrument which is to be introduced, but when the surgeon is gently pushed back the turning of the finger, the wrong position which the eye is about to take is immediately prevented. The method of using the eye, eye-bar, is not merely inadequate for young operations, but is the only perfectly *unadapted* one, which can be employed on this delicate organ, since all mechanical operations for this purpose, like the spreading sciss, which keep the eye steady by considerable pressure, or other contrivances, like Rousset's instrument, which does the same thing by means of a short pointed instrument, inserted to a kind of handle, and with regard to the sciss, in particular, and kind operations, are bound by necessity to be worse than that sciss. And, as a proof of this fact, they address to the numerous patients who come to me of the hands of such operators as employ these instruments, with a more, or less harmful loss of the vitreous humour, and other ill consequences, a statement which surely agrees with the observations of Wenzel and Wenzel.

While the late Mr. Ware contended with Wason and Beer, respecting the general question as to social, he remarks that "in some instances of children born with cataracts, he had been obliged to fix the eye with a speculum, without the aid of which, he found it totally impracticable to make the incision through the cornea with any degree of precision or safety." His specimen was an oval flag, the longest diameter of which is about twice as long as the diameter of the cornea, and the shortest about half as long again as that linear. Attached to the upper end of the specimen is a sort of shoulder, to support the upper eyelid, and by the lower rim it is fixed to a suitable handle. Some maintained that the operation is a laborious one, made for the purpose of causing surgeons to spend on both eyes with the right hand, the, namely, the right eye should always be operated upon with the left hand, and the left with the right, and he who desired leisure to equally share with both his hands, must always reach a longer.—*Lancet*, new Ser. August 1. p. 2, p. 241.—294.

Mr. Altschuler, whose great skill in operations on the eye is universally acknowledged, employs no apparatus for raising the upper eyelid, drawing the eye, which shows its membrane himself; and in Germany, this independent mode of proceeding has been particularly recommended by Hering. (Lecture after the dissecting apparatus library, for our golden Operative, Nov. West 1757.)

The preceding discussion, regarding the position of the assistant, the work of the case patient and his report, and the mode of filling the eye, are clearly those of Professor Barr. Whether these instructions are in every respect better than the following, which contain the substance of some other writer's experience, the interested reader must judge for himself.

Vol. 1—47

The patient should be seated rather low, opposite a window where the light is not vivid, and in such a manner, that the rays may fall vertically upon the eye about to be treated. The other eye, whether it is healthy or diseased, must, always be closed, and covered with a bandkerchief or any thing convenient for the purpose; or, so as to prevent sympathy between the two organs, that the motions of the one irremediably produce a disturbance of the other. The surgeon should sit upon a stool rather higher than that upon which the patient is placed, and in order to give his hand a greater degree of ascendancy in the various consequences of the operation, he will find it useful to raise the upper part of his face, by inclining his head slightly raised on his purpose, in a coal placed before his head. The chair or stool and pillow, was ought to have a high back, against which his head may be as firmly supported, that he cannot draw a hindquarter during the operation. The back of the chair must not slope backward, as that of a common one, but be quite perpendicular, in order that the patient's head may not be so shaken from the surgeon's hands.—(Edinburgh Dispensary, and Magazine, vol. 20, p. 24)

The presence of supporting the patient's head rather than the back of the chair on which he sits, thus keeping his head "fixed," as Beckwith has observed, is considered good practice because, that the loose motion of the mandible, even slight, is usually corrected by retraction, causes all a synchronous motion of the part supported. It is, however, which cannot fail to be beneficial, is, however, less to the operation of extraction and of anchoring. However, it is not at present the most correct posture, the maintenance of turning the back of the chair against the assistant and the patient may have their considerable disadvantages, in which it seems to be advantageous.

In certain cases, where the function of the eye and eyelids are mechanically affected with spasm; or where the eye is generally diseased, and with no disease in the mind, the disorder is the spasm oculi, treated by Haller, and approved by Scarpa, but possibly from nervousness; in young subjects, it naturally facilitates the cure.

The particular testaments of Wood and Warr, concerning the mode of fixing the eye, will be better explained in the description of the extraction of the cataract.

(3) COATING, OR DEFENDING OF THE EXTRACT, AND
 REACTION.

The question of coaching was once supposed to consist altogether in removing the spine from out of the state of tension, by means of a medicine, constituted for the purpose; but it is well known to be frequently of fatal or at least principle, even when the nature and resemblance of the material do not admit of the depression of the spine body. Experience fully proves, that the diseased lens, when broken and disturbed, with the needle, and especially when freely exposed to the contact of the upward lamina, by a proper location of its exposure, is gradually dissolved and resolved by the action of the atmosphere.

In fact, coming now upon a variety of operations; for it is altogether, not merely the displacement of its contents, not simply its displacement in any direction whatsoever, but only the breaking of its potential and the breaking of the fragments into the separate halves, but also from the mere disfigurement of the singular body, whatever its distortion is sometimes suffered, without any kind of dislocation or displacement of it as well with the whole. When, therefore, the uses of things are investigated, it is necessary to define precisely what constitutes it; if it is present, and for what part; either kind of case an application is demanded; for no argument of that passed day would come forward without it to one method of operation; and as the machine is broken, it is considering the advantages or disadvantages from any or all of the different operations for catalyst, it is absolutely necessary to consider, that, individual species is applicable to every species of the disease; that each kind requires an application for its kind of case, structure of a particular nature, and offering essentially from that which is found most advantageous to another. To collect these all the principles which can be used in any of the operations, thus a consideration of every case of catalyst to which it is used is not applicable, as

merely to confirm the subject, and has generally been done for the purpose of recommending some particular mode of proceeding, rather than to regulate those operations by the general principles of surgery."—(*Operative Surgery of the Eye*, p. 313b.) In this respect, the doctrines of Pelt, Calverley, Hey, and many are undoubtedly wrong, though these misconceptions are blended with many valuable and important truths. Hey, who is by no means a great advocate of depression, admits on many occasions that it is a useful and comprehensible way, but that it is not a firm and large extract either cannot be removed without injuring the seeing, and the attachment of the corpus ciliare to the vitreous humor, or not the enough to prevent the corpus ciliare from rising again at the first opportunity. Hence the former perceptions about the frequent return of the cataract, and other inconveniences, which possibly resulted, evidently produced cataracts, and severe inflammation, &c. But while Hey acknowledges the frequency of these ill effects of depression, he recommends the universal use of it, excepted at the present day, and the unlimited exhibition of it at relaxation, while continuing in applying the needle in a certain manner to the anterior surface of the vitreous body, and depressing the aqueous body into the vitreous humor, in such a way, that the front surface of the cataract is near the upper eye, the back surface the lower eye, its upper edge backward, and its lower edge forward; a change which, Hey says, cannot be made without an extensive separation of the cells of the vitreous humor. Hence, with few exceptions, this method attacks the common method of depression should be preferred.—(See now, *depression*, p. 2, p. 288.) And in this statement he is joined by Mr. Travers, who remarks, that the real objection to working in the breaking up of the fine texture of the globe of the eye, by the forcible depression of the lens.—"Whether it be depressed edgewise or broadwise, makes no difference in the result. It must still occupy a breach in the cells of the vitreous humor, and thus destroy and disorder this delicate texture and those connected with it. A slow, insidious inflammation, marked by a gradual development of the symptoms of disorganization, viz. disposition of vessels, inflamed humors, fixed vision, and galled eye, is too often the consequence. The slight amount of injury when the immediate effects of the injury are passed away, remains almost week and day, or divides and fades altogether. The advocates for reflexion seem to forget, that the vitreous, which is the same in both operations, as the rest of the eye. As to the position of the lens, I suspect little trouble to be done by the old method of depression, as however it is required to break a force for the removal than the hydropical lens, provided the depression is suited to the greater extent than is necessary to raise the inferior border of the pupil."—(*Synopsis of the Diseases of the Eye*, p. 416.)

The form of cataract needles should vary according to the object designed to be effected by the operation. The needles used by the late Mr. Hey, that recommended by Deane, and again employed by Best, are the principal ones.

The length of Mr. Hey's needle is sometimes less than an inch. It should be sufficiently long if it is not curved somewhat at its end. It is round, except that the point, where it is made flat by grinding two opposite sides. The flat part is ground gradually thence to the extremity of the needle, which is uncurved, and ought to be made as sharp as a lancet. The flat part should be at least about an eighth of an inch, and no sides be parallel. From the part where the needle should be flat, the diameter gradually increases towards the handle. The flat part is one-fourth of an inch in diameter. The part which is curved the handle is one-twelfth of an inch. The handle, which is thick towards a half an inch, is made of light wood, stained black. It is cylindrical, and has a large, very small at the top end, which corresponds with the edge of the needle.

Mr. Hey mentions the recommendations of this instrument in the following terms:

1. "It is only half the length of the common needle; and thus gives the operator a greater command over the movement of the point, in removing the crystalline lens as well as leaving the retina. It is also of more convenience than the hydropical needle, because the point of the needle has penetrated the globe of

the eye, before he has an opportunity of seeing it through the pupil; and it ought to be brought forward when it has reached the lens of the pupil. Now it may advantageously form a better judgment respecting this circumstance, when the length of the needle may not be so much the diameter of the eye, than when it is seen only by the ordinary length, which is nearly the same. The purpose of the needle is perhaps the same when the operator is so anxious that the point should be seen through the pupil.

2. As the needle becomes gradually thicker towards the handle, it will remain fixed in that part of the vitreous, in which the operator has pushed it, while it employs its point in depressing and removing the cataract. This diamond-shaped needle, by sliding a second layer in clearing that part of the vitreous which remains in the vitreous, between cataracts, and is with difficulty prevented from sliding backward against the vitreous processes, while the operator is giving it those motions which are necessary for depressing the cataract.

On the same account the common spoon-shaped needle may enter some of the vitreous humor, so as to escape during the operation, whereas the flat and diamond-shaped needle would be so much displaced and injured, whereas the needle which I use, making by a small aperture in the vitreous, and taking up the aperture completely during the operation, is not so liable to the vitreous humor to escape, and so as to prevent the vitreous and ciliary processes from.

3. This being true in preventing cataracts, but in spoon-shaped needles, having two sharp edges, which grow gradually thicker towards the point, will be liable to wound the retina, if it is introduced not near the vitreous humor, with its edge in a horizontal position. Besides, in whatever manner it is made to introduce, one of its sharp edges may be turned towards the vitreous, and so as to prevent the cataract; and in the various motions which are necessary in this operation, the vitreous processes are certainly exposed to more danger than when a needle is used which has its flattest edge.

4. If the needle is pushed into the eye, the diamond-shaped needle, the operator's intention is to bring the flattened part over the center of the crystalline. It is impossible, on any case, there is great danger of injury of the retina beyond the circumference of the operation, and reaching half of the ciliary processes, or the vitreous humor, the membrane of the eye.

Mr. Hey remarks, that the needle will pass through the vitreous with ease; depress a firm cataract gently, and break down the texture of one that is soft.—"If the operator finds it of use to bring the point of the needle into the anterior chamber of the eye, he may offer the needle, he may do this with the greatest safety, for the edges of the needle will not wound the retina. He should, if the operator is the end of the needle, then the point, property in the center of the pupil, so that its rounded edge is in the eye, and disengaged from the corneal epithelium, as the point does, but fixed beyond the point of the needle by which the insertion is made, the extreme part of the needle being over the iris process."—(Hey.)

Deane employs a very slender needle, possessing sufficient firmness to enter the crystalline without laceration, and having a point which is slightly curved. The curved extremity of the needle is the same in diameter as necessary, strong at its other end, and is not nearly, rounded with two oblique surfaces, forming at the middle a gentle curvature, and so rounded along to the very point of the instrument; there is a notch on that side of the handle, which corresponds to the convexity of the pupil. The purpose of the hook is to serve and use advantage of the handle, when they are used in operation of Best's method, I have, having it ready of the greatest length than the purpose of the operation intended. A cataract needle is sufficiently long when it does not exceed, it must, in any length; this admits the operator a greater command over the motion of the point, and enables him to push where necessary, low to it, but penetrates the globe of the eye, before he has an opportunity of seeing it through the pupil. When Hey's needle is pushed, it always therefore be of a greater length than the operation requires. The needle has sharpness, and possesses the property of not so easily as any straight, or oblique needle, Deane, and by means of the wheel.

stored in the vessels from the aqueous humor. Mr. Port, in treating of this circumstance, viz. the entrance of the fluid contents of the capsule into the aqueous humor, observes, that in the first stage of this disease, and previous to the formation of the opacity, the production of all the blood which can be carried into the fundus of the eye depends on the action of the blood vessels and the capillaries.

When the cataract is of a soft and watery description, the particles of which it is composed will thoroughly unite in efforts made with the hands to depress them, and will continue behind the pupil in the state of vision. This has been observed in one instance, but for the efficacy of surgery, and may really seem to be an exception to an ordinary circumstance. It often happens in the operation of extraction, that fragments of opaque matter are occasionally overlooked and left behind; yet the patient complains that such matter is frequently perceived in the distance. Supposing a cataract extruded to be sufficiently broken and dissolved in the first operation, and that consequently the elements did not necessarily recombine it, such a state might possibly require a reoperation of the formation, but this does not generally occur, and is the worst that can happen. It is quite impossible to determine, in what effect will result from the best method of treatment of a cataract, as every operation has its own advantages, and while, in others, a reoperation of the operation becomes necessary for the removal of vision. Even where the whole has been removed, and the pupil is left in its natural state, the elements have succeeded the necessity for the same result. The disappearance of the opaque particles of cataract, as in vision and in all cases, a fact of such consequence, that, as appears from the authority of Barrois and others, it was considered even necessary to the discovery of the system of the cataract in the body. Indeed, the various circumstances of Scarpa and others so strongly corroborate the theory which I have given of the progress of the cataract in the two chambers of the vitreous humor, and particularly in the anterior one, that from the moment the case is discovered to be a soft or watery cataract, it strikes upon the ordinary practice any further attempt to depress it, is the farthest to be feared. Mr. Port observes in this circumstance, though no attempt of this kind, but contented himself with a free incision of the capsule, and after taking the fluid matter out, and between his finger and thumb, with the body of the crystalline lens, all the parts in their natural situation, where he mostly ever when then has it immediately in entirely as not to depress the earliest vestige of a cataract. This method was proposed several years ago by several authors, and though at first it was not generally received, it has since been proved the firm part of such operation, though the pupil and the vitreous humor, where it is most dangerous, without touching the lens itself, or the vitreous humor, but at the same time, that it is thought this method wrong, and no account of its efficacy, but at the same time, that it would be to produce in irregularity in the fundus, one of the most dangerous attending the operation of extraction. But the efficacy of the pupil after extraction, seems to be proved either from an actual observation of the use of a suitable situation of the pupil, by the passage of light through it, or a part of which would be to produce in the fundus the same position of a cataract, and into the vitreous chamber. Hence, it does not seem unreasonable to expect this very efficacious method of treatment. It is well deserving of consideration, that Mr. Port, who has several times, with the vitreous humor, and very frequently with aqueous humor, and the vitreous chamber, makes this remark. Indeed, if the cataract would, in all cases, be brought into the vitreous chamber of the eye without injury to the eye, it would be the best method of performing the operation. What the same author also observes, of a subsequent part of the work, is strikingly corroborative of the efficacy of Barrois's practice. The progress of the disease previous to the operation, the advance action of the crystalline capsule to the extent of the diameter of the pupil, in a moderately dilated state; in rendering the pupillary substance of the cataract transparent, and in passing the fragments through the pupil into the vitreous chamber, where they are gradually absorbed.

The great advantage of such a method, indeed, is by Scarpa, who also is generally removing the capsule at the same time with the lens, from the passage of the rays of light is the cause. Scarpa, however, this desirable result, by which the patient is extricated from the danger of a secondary cataract, is not effected, does not take place. What most frequently succeeds the secondary cataract, is the opacity of the vitreous half of the capsule, which, not having been removed, is continually broken in a vitreous situation, continues more or less entire in its original situation, afterward becomes opaque, and thus produces the same obstruction of the rays of light in the end of vision. Sometimes the secondary cataract, sometimes, and sometimes both behind the pupil, in the form of membranous folds, appearing behind in the vitreous humor, and sitting up the pupil; at other times, it appears in the form of membranous structures, with their bases united to the membrane of the capsule, and their points directed towards the center of the pupil. When there is only a vitreous cataract, the capsule is suspended in the posterior chamber, because, though it is not necessary for the patient to submit to another operation, vision is tolerably perfect, and further the same patient of opaque matter will undoubtedly disappear. But when the secondary cataract is present, and of a cataract of opaque fragments of the capsule, accumulated in an either in a great degree of opacity, or in the pupil; or when the cataract, composed of the whole anterior half of the capsule, is present, is a great operation, and continuing subject to an internal solution, it is indissoluble in aqueous humor. In the latter case, the first case, there may be good reason to hope that the solution of membranous fragments, by their absorption, yet it would be impossible to detach the points of the folds and insert in a state of opacity and absorption, when a soft, the whole cataract would remain, as in a very short space of time, in the progress of this part, most of the cataract. In the second case, says Scarpa, it is absolutely independent, and while the membrane is allowed to descend, cataract, the opacity is less complete, and may even pass over a larger portion of the pupil. He advises the operation to be performed as follows: when the opacity in the eye is determined by a portion of membranous folds detached from the membrane of the capsule, the curved needle should be introduced with the most precaution, keeping its curvature towards the point of the cataract, and with which the mass of opaque matter; the surgeon is then to take the point of the needle through the pupil, and to push through the opening regularly, one after another, all the opaque portions into the vitreous chamber, where, as we have before noticed, all weights seem to be carried on, from vitreous fluid behind the pupil. All endeavors to depress them into the vitreous chamber Scarpa has failed to be in vain; for activity is the cataract, and the vitreous fluid when they are trapped in the pupil, as it is not its own natural curved, but by a current; the whole second case the vitreous chamber, besides being incapable of blocking up the pupil, they do without inconvenience at the bottom of this cavity, and in a few weeks are entirely absorbed.

When the secondary cataract, cataract consists of the whole anterior layer of the crystalline capsule, or of several portions of it connected with the membrane of the capsule, Scarpa, after repeatedly having the point of the needle towards the pupil, passes the curved needle into the vitreous chamber, and passing the point of the instrument through it, then, having turned it again backwards, he carries it as near as possible to the attachment of the secondary cataract, and after passing the capsule, or such portion of it as is necessary, and sometimes carefully taking the handle of the instrument, he draws and draws, so as to draw the capsule round its extremity, so that it breaks the cataract, so far as it is possible, at every point of its attachment. The portions of membrane by the veins separated from their attachment, are then, cautiously pushed, with the point of the curved needle, up the pupil, through the pupil into the vitreous chamber. As these membranes are the vitreous matter, and the vitreous matter, it is not to be feared, for they will certainly be absorbed. Scarpa, in the production of bad symptoms after the operation, and notwithstanding the duration of the operation, and the success

section of the cornea is completed," &c.—(See Lister's Short Inquiry into the Principal Causes of the Chronical Inflammation of the Eye, 1825.) During the advances required to Jaeger's knife are those of not injuring parts in the inner angle; of not making the incision too small for the entrance of the lens; and of loss of the aqueous humor being discharged previously to the iris being out of danger. The weakness of Richter, Scarpa, &c., and others, about the position of the patient in the operation, and the mode of fixing the eye, have been already noticed in a foregoing section.

The operation is to be on a spot of the cornea just upon a considerably higher level or chair than the face; as already explained, and his legs are to be placed on each side of the patient, and his right leg sufficiently raised, by a stool for his elbow to rest upon his knee, while the knife is on a level with the patient's eye.—(See Guthrie's Operative Surgery of the Eye, p. 255.)

When the right eye is to be operated upon, and the operation is to be done according to the preceding directions, the surgeon must of course use his left hand; but if he be unable to perform it, the patient must be placed on his back on a table, or on a mattress, or a firm bedstead with a head, so that the operator may stand behind without inconvenience. The head being supported on a cushion, the operator raises the upper eyelid himself and turns the eyeball, while an assistant depresses the lower lid, if necessary. The incision is then to be made with the same precautions as in the other method, the knife being held with its edge towards the thumb, and the little finger, beyond the temple instead of the cheek. The direction of the cut is upwards in this manner is the operation generally performed by Mr. Alexander for both eyes, when not specially contra-indicated.—(Guthrie, p. 255.)

Robert Wilson, himself of the last consequences of undue pressure, never was able to see by the eye at all at the period of making the incision.

The late Mr. Ware did not appear of this plan of leaving the eye naked. The danger likely to arise from its bare pressure, he observes, can only take place after the instrument has been set spring into the eye; but the pressure which he recommended is to be removed, the incision the knife is carried through the cornea, and before any attempt is made to divide the lens downwards. To understand this subject better, however, the reader should know, that Mr. Ware divided the incision of the cornea into two distinct processes; the first of which may be called punctation, and the second section. He says, says Mr. Ware, as the knife fills up the aperture in which it is inserted, that is, until it has passed through both sides of the cornea, and its extremity has advanced some way beyond this tissue, the aqueous humor cannot be discharged, and pressure may be continued with safety. The punctation of the cornea being completed, the purpose of pressure is fully answered; and if such pressure is continued when the section of the cornea begins, instead of being useful, it will be harmful. To avoid all bad effects, Mr. Ware recommends the wound to be cut in the following way.

The operator is to place the face and middle finger of the left hand upon the inner commissure, just below and a little on the inside of the cornea. At the same time, the assistant, who supports the head is to apply one or, if the eye projects sufficiently, two of his fingers upon the conjunctiva, a little on the inside, above the cornea. The fingers of the operator and assistant thus opposed to each other will fix the eye, and prevent the risk from closing. The point of the knife is to enter the outside of the cornea a little above its transverse diameter, and just before its connection with the sclerotic. This is the best point, it is to be pushed on slowly, gradually, without the least interruption, and in a straight direction, with its blade parallel to the eye, so as to pierce the cornea towards the inner angle of the eye on the side opposite to that which is first visible, and which is the best part of it is seen to emerge beyond the inner margin of the cornea. When the knife has reached so far, the punctation is completed. The front part of the blade is now between the cornea and the iris, and its cutting edge below the pupil, which of course is out of all danger of being wounded. As every degree of pressure must now be taken off the eyeball, the fingers both of the

operator and his assistant are instantly to be removed from this part and shifted to the eyelids. There are to be kept under by gently pressing them against the edges of the iris; and the eye is to be left entirely to the guidance of the knife, by which, says Mr. Ware, it may be raised, depressed, or drawn in either direction, as may be found necessary. The aqueous humor being now partly, if not purely, exhausted, and the cornea of course rendered flaccid, the edge of the blade is to be pressed slowly downwards, till it has cut its way out, and separated a little more than half the cornea from the sclerotic, following the same oblique direction marked out by the punctation of the eye to the iris.—(Ware.)

In the eyes of some persons, the iris is so dense, that it almost impossible to compress the section of the cornea without wounding the iris under the edge of the knife, thence the cornea is gently rubbed downwards with the finger; one of the most important directions, according to Mr. Ware, is Wenzel's whole book.

If the edge of the knife should irritate too much the iris, and its direction be not exactly the same, the cornea will be too small, and tearing it down is proper to be feared. In this case, there will be great difficulty in extracting the cataract, and the danger afterward may almost equal that of the contrary, because of the instrument to extract the lens, the force, and its direction, be not changed, the incision will approach too near the part where the iris and sclerotic meet, and there will be great danger of wounding them. This accident may be prevented by gently raising the conjunctiva between the blades, and the blade below the greater diameter.—(Ware.)

The late Mr. Ware had seen operations through a fear of wounding the iris, rendered unnecessary by the instrument at a considerable distance before the edge of the cornea and sclerotic. In consequence of which, the incision often ran wide of the cornea. At the other time, he would be the only cause of the rupture, although then above downwards it was fully large enough for this purpose. Mr. Ware was sometimes observed, that though the punctation of the cornea, from side to side, had been properly made, and its section afterward, to all appearances, efficiently completed, yet, on account of the incision on the eye, the incision the iris, from the side of the cornea, and consequently, though the incision appeared externally to be of its proper size, internally it was much too small to be returned to its usual connection. In this case, the iris was said to be collapsed by means of a pair of curved blunt pointed scissors, which should be introduced in the part where the knife first entered the cornea.—(Ware.)

Beer subdivides the first stage of this incision into four, each of which, he says, causes the excruciating pain, if it be wished to make the incision in the iris in every respect proper: the first is the introduction of the knife through the cornea into the anterior chamber; the second is drawing the knife towards the pupil where its point is to be brought out again; the third is bringing out the point and guiding the knife in separating the iris from the cornea, and the fourth is the finishing of that incision. As Beer wishes a completely well-made incision in the cornea, that, in the first place, he is so cautious not to let the incision escape from the eye without the slightest impediment; and it will be large enough, if care is taken to make one-half of the cornea parallel to the eye. Secondly, it will be of proper shape, its margin not being irregular, now pointed, but evenly rounded. In general, the first, or greater inconvenience can happen, that of having too small an incision in the cornea; the iris, when the incision is pressed out of such an opening, portions of it are always left behind which afterward cannot be extracted without trouble; and though the sight may be at the moment restored, it will be lost when the eye is not afterward guided by the effects of inflammation. When the incision is irregular or small, its edges cannot be put exactly together so as to be joined by the first cicatrix, which, however, is highly necessary, and the consequence is a white eye, which is always produced with inflammation, and forms a greater or less permanent impediment to vision downwards, though the patient be capable of

seeing the position of the eye which are straight before him.

According to Beer, when the knife is to be introduced, the patient should enter the corner, about one-eighth of an inch from its apex, and one-fourth of a line above its anterior diameter. Directed obliquely towards the pit, with its edge turned downwards, by which means the point will pass immediately into the anterior chamber. As soon as it has arrived there, which is indicated partly by its being extremely firm and within the space is exposed, and partly by the tarsal reflex, such a direction is to be given to it that its point may be raised from the place of its entrance (near) in a direct line towards the intended place of its exit out of the corner, for a little higher; while the posterior surface of the blade is to be covered across the anterior chamber nearly parallel to the cornea. The knife is to be constantly passing, under the eyelids, not too slowly, with its point continually directed somewhat upwards above the pit, where it is to pass out again, and the point struck near the inner wall of the cornea; but in the transverse passage of the knife, its edge should not be suffered either to go nearer to the farther from the iris, or away from the iris backwards or forwards more, the upper angle of the wound, when the eye is drawn forward, immediately escapes, and the iris not only falls down against the posterior surface of the blade, but sometimes from under the edge, so as to throw the spring upwards into the greatest weakness. If the point of the knife has not been accurately brought out, the surgeon is to continue to push it in, holding the point downwards, or making a waving motion with it, until the last stage of the operation, viz. that in which the incision is finished. However, as soon as the point of the knife has passed out of the corner, and pointed the lower cornea, attention must be paid, first, to that part of the blade which is in the anterior chamber, so that the iris may not fall under the edge, and the knife may not take an erroneous direction; secondly, to the point of the knife, which continually projects more and more, so that the iris cannot be torn, and thirdly, to the wound, which accident, though trivial in itself, would make the improved patient suddenly and unfortunately show that he has failed. The only way of preventing this injury, says Beer, is regularly to incline the handle more backwards and downwards, in proportion to the point passes further out of the anterior chamber. Thirdly, at the period when the last part of the incision ought to be cut, the knife should be pushed so very slowly, or otherwise the iris, and with a part of the vitreous humor, may be disengaged, as soon the handle of the eye and acting and removing this organ with the greatest force, and the iris, of course, especially, will come projecting, and the cornea will be torn through, come against the iris, and is apt to be wounded. At the time when the cornea begins to fall down, the surgeon, the assistant is to let the upper eyelid cover the eye, and a few efforts are to be allowed for the patient to move his head.

In the second stage of the operation, Beer directs the assistant again steadily to hold the patient's head in the same manner as during the cutting of the incision, but the upper eyelid being now held carefully and effectively fixed, without touching the eyeball in the least, as being the edge of the finger project beyond the edge of the tarsus. The operation is to be done in the lower eye with his forehead, which is to be pushed away from the eye, but gently against the lower part of it with the assistance of the hand, by which means the cornea-lens or crystalline may be more readily and easily introduced under the flap of the lower eye, the pupil, while the point passes, and the projection of the cornea thereby produced, considerably enlarges the pupil, and facilitates the proper division of the capsule. In order to complete the latter object, the surgeon introduces one of the sharp edges of the capsule-needle, with the point directed towards the inner chamber, between the cornea and the vit. the wound in the former of these membranes being opened as large as possible, lest the atmosphere destroy the iris; a circumstance of which Beer extremely great apprehension. After the crystalline has been carefully passed to the inferior margin of the pupil, its lower sharp edge is to be applied to the capsule of the lens with its point directed upwards, and one of its flat surfaces towards the

inner, and the other towards the aqueous chamber. The incision is now strictly to cut through the capsule, by making it small distances down one another, repeated perpendicular strokes with the edge of the needle. When the handle of the instrument is to be half turned round out of axis, and smaller strokes are to be made with its edge in a somewhat oblique direction, by which means the anterior layer of the capsule will be removed many separate fragments, some of which, in the third stage of the operation, are taken out of the eye together with the vitreous, and the risk of a secondary cataract of the posterior layer of the capsule is in a great measure removed. When the crystalline has been so broken, it is to be withdrawn from the eye in the usual position in which it was introduced, and the second stage of the operation is then finished. (Beer, &c. p. 59.)

I believe no better instructions than the foregoing can be delivered, respecting the most advantageous method of dividing the capsule. They are infinitely better than those given by Wenzel and Wenzel. As soon as the point of the corner-knife had arrived against the pupil, Wenzel used to incline it partly backwards, and then pass the capsule; but Mr. Wenzel very properly objected to this plan, which, however, might serve to effect the division of the capsule, was attended with no advantage to the patient, and could not be so different and safe as the mode of making the division of the capsule a distinct part of the operation.

Indeed, Wenzel himself did not recommend opening the capsule of the crystalline in this way when the pupil was much contracted, and the insertion of the capsule-needle indistinctly seen and motionless, in which the posterior chamber was large.

And still the contrary after the division of the capsule, Wenzel and his father used to express it that the capsule, one side, that is, the middle part of it, which is densest, having its cutting necessary a little interrupted. This point, which they allowed to be made of metal gold, in order that no glutinous matter when the capsule is torn is in different directions, because, positive, is fixed in a double two inches and a half is broken, and making it that of the corner-knife. At the other extremity of the same handle a small aperture was made, made also of metal gold, which is of use for evacuating the cataract.

The late Mr. Wenzel's method of opening the capsule will be hereafter noticed.

When the incision in the cornea has been completed, and the capsule effectually divided, the cataract, as Beer observes, advances into the pupil immediately behind the capsule-needle, and if there be the least motion in the eye itself, it is generally motion discharged. Under these very favorable circumstances, however, it sometimes happens that a portion of the gelatinous or vitreous surface of the cataract is detached at the margin of the pupil, as the capsule body is pushed out, and, therefore, in the second stage of the operation, Beer recommends having the eye motion always ready, which is to be maintained for the capsule-needle, and employed for evacuating the lens, the capsule being falling back into the posterior chamber, in the following manner: as soon as the capsule-needle, that is, the point of the cataract out of the pupil, a portion of it will be separated at the edge of that opening, it should introduce the scoop at the lower and outer edge of the cataract capsule, between the pupil and the eye, so as to be able to keep the part of the cataract which is ready to break off, close up behind the rest of it, and bring the whole out of the eye.

But, says Beer, when the third stage of the operation, viz. the removal of the cataract from the eye, cannot be so readily accomplished, a precaution must always be taken to an impression is to be made in the second or in the division of the capsule, but sometimes proceeding from a want of proper action in the eye itself, the operation, if he feels convinced that the lens does not lie in the first or second stage of the operation (as being cut) it would be necessary to endeavor to remedy what is wrong, should assist in preventing the discharge of the cataract. There are two instances of being thus, and it is not a matter of indifference which is selected; for the second should be adopted only when the first will not succeed. Hence, says Beer, the operation, like a well-considered, must be level in the action of the eye itself, which is to be at a certain degree, and it is to proceed immediately

des, viz., with the convexity turned towards the abdomen, or with the convexity directed downwards, in the first stages of the operation. Of course, the latter plan requires the instrument to be turned so as to place its convexity upwards, as soon as the hook has arrived in the prostatic urethra, and hence the French surgeons call this method the "tour de main." This motion is accomplished by some practitioners, who never beginning the operation in corpore persons with the handle of the catheter placed towards the left groin.—(See *Lectures, Almon, des Chir. F. & P.* 184, *Edinb.* 1827.)

The operation may be divided into three stages. In the first, the catheter passes, in the male subject, that portion of the urethra which is surrounded by the corpus spongiosum; in the second, it passes the membranous part of the canal, situated between the bulb and the prostatic gland; and in the third, it enters the gland and the neck of the bladder.

In the first stage, little trouble is usually experienced; for the canal is here so supported by the surrounding corpus spongiosum, that it is almost rarely so pressed into the folds of a penis, in which the end of the instrument must be wedged.

When the catheter is to be introduced with its convexity towards the abdomen, and the subject is in the supine position, the thighs are to be separated, and the legs moderately bent. The surgeon is to approach the penis, and to lead the penis between the thumb and fore-finger of the left hand, which are to be applied on each side of the corpus glandis, and not at all to the under surface of the penis, so as to avoid pressing upon the circumference of the urethra. After the catheter has been well introduced, its handle is to be held between the thumb and fore-finger of the right hand, and to rest with the back of the little finger upon the patient's abdomen, in the vicinity of the navel. Now, while the handle is applied to the side of the body, the back is to be introduced into the urethra, the penis being extended and drawn forwards, as it were, over the instrument, while the latter is gently pushed on until its hook has reached the arch of the penis. When the penis cannot be drawn further over the catheter, the back has arrived in this situation, where it is kept in front of the arch, and is pressing against the posterior wall of the urethra. At this particular moment, the handle is to be depressed towards the patient's thigh, and the surgeon's well secured generally between the end of the catheter at once through the prostatic portion of the urethra into the cavity of the bladder. It then, as soon as the back of the instrument has passed under the arch of the penis, and the surgeon very slowly brings the handle forwards or downwards, the back is elevated and slides into the bladder. In this stage of the operation, the penis must be allowed to sink down, and not be kept tense, as this would only render the passage of the instrument more difficult.

The operation, however, is not always successfully accomplished in this manner. The back of the catheter may be stopped by the os pubis; it may take a wrong direction, so as to push the membranous part of the urethra to one side or the other; or it may be stopped by a fold of the lining of the passage.

The first kind of instrument is best avoided by not depressing the handle of the catheter too soon; that is, before the point has passed beyond the arch of the penis. When the membranous part of the urethra is pushed to one side or the other, the instrument ought to be withdrawn a little, and then pushed partly on in a different direction, but if one experiment is unsuccessful, the index finger of the left hand may be introduced into the rectum, for the purpose of supporting the membranous part of the urethra, and guiding the extremity of the catheter. The passage of the catheter through the membranous part of the urethra, and especially the attempt to get the extremity of the prostatic urethra, are attended with risk of hæmorrhage, which is frequently produced by rough, accidental strokes when they are violent, and renders the following, much more of the same.

When the prostatic gland is entered, the urethra, just as it approaches the bladder, makes a more sudden turn upwards than is usual. The end of the catheter, therefore, should be made bent upwards thus in such cases.

In the third stage of the operation, the back of the

instrument has to pass the prostatic gland and neck of the bladder. The principal obstacle in this passage is this situation some short space of the back of the bladder and urethra in the prostatic gland, and these the instrument being pushed against the prostatic gland, instead of into the circumference of the urethra through it. The first impediment may generally be removed by holding a firm pressure, and gently rubbing the prostatic gland, before attempting to push the catheter further into the passage. The resistance caused by the prostate is best rid of, more at increasing the point of where it is most curved than its other part. Sometimes the surgeon himself passes the point forwards due to pain, by means of his finger in the rectum, and thus prevents the passage of the catheter, by increasing the sudden curvature of this part of the urethra. Hence, as Richter observes, it is a very important matter, never to introduce the finger so far into the rectum as to press on the prostatic gland itself.

When the catheter has passed round the penis, and is just about to enter the neck of the bladder, is the critical moment of which may be seen whether a surgeon can or cannot manage the operation with skill; for if he knows how to pass the instrument, he is suddenly, but not violently, changed into a doctor. He introduces the handle with a particular kind of address, and raises the point, which, as it is bent suddenly upwards, enters the neck of the bladder, and the crime bursts out in a jet from the mouth of the catheter.

There are two additional points to be remembered, and passed, as they first began, in coming to the penis, in the supposition that by directing this part, they straighten the urethra and make it straight, whereas they straighten only that part of the canal into which the catheter has already passed.—(John Bell's *Principles of Surgery*, vol. 2, p. 212.)

When the catheter is to be introduced with its convexity downwards, or by the "tour de main," the back is to be passed and the urethra, and the penis drawn over it, as it were, as in the foregoing method. In other words, the instrument, well held, is to be introduced, with its convexity upwards, as far as it can be without being bent. As soon, however, as the end of the catheter has reached the point at which the urine begins to flow, a curve under the penis, the surgeon is to make the penis and the instrument perform a simultaneous movement, by inclining them towards the right groin, and then towards the left groin. In the execution of this movement, care is to be taken to keep the back of the catheter stationary, so that it may be the centre of the movement, and simply revolve upon itself. This part of the operation, the object of which is to turn the convexity of the catheter upwards, ought to be done very slowly, a large sword being made with the handle, while particular care is taken not to retreat nor make the back from its position. The handle is then to be depressed, and the operation finished exactly in the same manner as when the first plan is pursued. As Desault properly observes, the only circumstance in which the two methods differ is, that in one the same thing is performed by two movements, which is done in the other by one; so that the operation is rendered more difficult and painful. Hence, many judicious masters strongly prefer practice the "tour de main," except when their patients are very robust, or placed in the position usually chosen for lithotomy, when other modes of introducing the catheter would be less convenient.

The depth to which the catheter has entered, the position of any swelling of the urethra, in the neck of the bladder, when retained upon its axis, and the point of the time, are the circumstances by which the surgeon knows that the instrument has passed into the bladder.

According to the experience of Desault, the practice of gradually lifting up a part of the urethra, after the catheter has been introduced, is by no means advantageous. He is, however, of opinion, that the opposite extreme, that is to say, of letting the urethra flow out of the catheter as fast as it is inserted; for then the bladder is kept constantly emptied, and the detrusor muscle will not be likely to recover its tone. When the bladder is constantly empty, it is liable to come into contact with the end of the catheter; a distension which has sometimes caused considerable irritation, pain, and even absorption of the urethra. Be-

sides these inconveniences there are some others; the catheter is more obstructed with mucus, and covered with incrustations, than when it is closed with the stylet. The patients are likewise obliged to remain in bed, where they are either wet with their urine, or compelled to have incessantly a pot for its reception. The best practice therefore, seems to be that of leaving out all the urine as soon as the catheter is introduced, and then closing the instrument until the bladder has become moderately distended again; for experience proves, that with moderate distention and relaxation of the muscular fibres of the bladder, alternately kept up, have the same good effects upon that organ as moderate exercise has upon other parts of the body. When a catheter is to be left in the urethra, it should always be properly fixed with a narrow piece of tape, or tied if it is apt to slip out, or even pass too far into the urethra.

For this purpose, most surgeons use cotton-wool, which they tuck in the rings, or round the external end of the catheter. The inconveniences of this thread are then carried some way along the direction of the penis, when they are tied together, and afterwards conveyed in opposite directions round the part all they most apprehend it, where they are tied in a knot. When a silver catheter is employed, a tape or narrow ribbon is passed through each of the rings, and extended to each side of the penis, where it is fastened to a circular bandage. Mr. Huxley remarks, that the ingenious but trifling contrivance afterwards adopted, of tying two or three rings are fixed on each side of a thin piece of tape, and the ring of the catheter is fastened to any of these with a piece of tape.—(On the Venereal Disease, vol. 2, p. 120.) He also notices another method: When the catheter (copper) is fixed in the bladder, the other end is drawn downwards nearly in a line with the body. To keep it in this position, we may take the common strap or belt part of a bag-truss with two thigh straps, or the fixed to it or hooked end, and coming round each thigh forwards by the side of the scrotum, to be fastened to the belt, where the end of the bag may usually find it. A small ring in 1794 may be fixed to each strap just where it passes the scrotum or root of the penis, and with a piece of wool tie the ends of the catheter may be fixed to these rings, which will keep it in the bladder. It seems Mr. Huxley did not like Broust's contrivance of leaving the catheter undisturbed, and he adds, therefore, "a bit of rag about four or five inches long, with a hole at the end of it, passed over the external end of the catheter, and the lower end allowed to hang in a basin placed between the thighs, will catch the water, which cannot discharge itself from the catheter, and keep the patient dry; or if another piece is introduced into the catheter, it will answer the same purpose."—(Op. cit. p. 121.) The following, which is the French method of retaining the catheter in the bladder, is the most convenient with which I am acquainted:—A muslin ring, the circumference of which should be more than sufficient to encircle the penis, so to be covered with cloth, and four long pieces of tape, with the same number of short ones, attached to it. This ring, enclosing the penis, is fixed against the scrotum by the long pieces of tape, which, encircling the penis in different directions, meet and are tied posteriorly. One of the short pieces is slipped through the ring or over the groove of the catheter, as each side, and being tied to its fellow, fixes the instrument securely in the bladder."—(See *Journal of Operative Surgery*, p. 155.) But there are numerous modes of fixing a catheter which need not be specified; for although the use of instruments, the introduction which should be observed in slipping them are the main things to be understood. These are, first, never to fix a catheter in such a way that too much of the instrument projects into the cavity of the bladder (*Lithotomy, Perforation de la Vessie par les Nouvelles*, &c. *Revue Méd. Nov. 1825*, p. 226); and secondly, to be careful that the thread or tape which is applied will not chafe and irritate the parts.

Mr. Hey has offered some good practical remarks on the introduction of the catheter. If, says he, the point of the catheter be less turned up than the urethra, the point will be pushed against the posterior part of the prostate, instead of following the course of the canal. The posterior part of the urethra has a weak resistance to it which can support it, and no considerable degree of force will push the point of the catheter

through that part between the bladder and the rectum. If the accident is avoided, still the point will be pushed against the prostate, and cannot enter the bladder. Mr. Hey believes, that the truth of this is illustrated by the microscope which is denied. Whenever the catheter stops at the prostate, soon elevating the point of the instrument with a finger introduced into the rectum.

Mr. Hey takes notice of the impropriety of passing forwards the point of the catheter before the bladder is sufficiently depressed, as the point would seem to be horizontal direction, and be likely to rupture the posterior side of the urethra.

For a facility arising from the inflamed and dry state of the passage (which certainly I should conceive may never be cured), Mr. Hey says, may be obtained by the previous introduction of a sponge well covered with lard.

In order to pass the catheter, Mr. Hey places the patient on a bed, in a recumbent posture, his head ascending to, or projecting a little beyond, the edge of the bed. If the patient's feet cannot rest upon the floor, Mr. Hey supports the right leg by a stool or by the hand of an assistant. The patient's head and shoulders are elevated by pillows; but the lower part of the abdomen is left in a horizontal position. Mr. Hey constantly introduces the catheter with its curvature towards the scrotum, and having gently pushed down the point of the instrument, till it becomes stopped by the curvature of the urethra, under the symphysis pubis, he turns the handle towards the thigh, pressing at the same time its point. In making the turn he sometimes keeps the handle at the same distance from the patient's shoulders, and sometimes makes it gradually rotate; but in either manner, he avoids pushing towards the point of the catheter any farther than is necessary to carry it just beyond the angle of the symphysis pubis. When he finds this point to period that must be, pulls the catheter point towards him, looking, as it were, the point of the instrument upon the penis. He then depresses the handle moving it towards the angle of the pubis; the course of which is the angle of the pubis. When the handle of the catheter is brought into a horizontal position, with the convex side of the instrument upwards, he pushes towards the point, keeping it close to the internal surface of the symphysis pubis; for when passing in this direction it will not touch upon the prostate gland, nor upon the membranous part of the urethra.

If the catheter were a flexible catheter, covered with elastic gum, it is of great consequence to have the outer ends of some thin malleable substance, and of a proper thickness. Mr. Hey always makes use of brass wire for the purpose. If the stylet is too slender, the catheter will not preserve the same curvature during the operation; and it will be difficult or unable the point just upwards behind the symphysis pubis in a proper direction. If the stylet is too thick, it is introduced with difficulty.

When the stylet is of a proper thickness, this instrument has one advantage over the silver catheter, which is, that its curvature may be increased while it is in the urethra, which is often of great use when the point approaches the prostate gland. In all cases where a elastic gum catheter is employed, care must be taken that it does not pass unnecessarily far into the bladder; and, if it is too long, a part of it ought to be cut off, or a shorter one employed.

In many cases elastic catheters, fixed with a permanent curvature, so as to affect of being introduced without a stylet, are mischievous.—(M. J. Chalmers, *Revue des Chirurges*, 2. p. 127, *March* 1827.)

When the proper resistance will a silver catheter do not succeed, the surgeon must change it, taking a bigger or more slender one, with a greater or less curve, according to your observations as to what may be the best attempt. But if the catheter has been of a good form or occasionally one, yet has not passed easily, be steady, instead of closing a rigid catheter of another size or form, take a flexible one for his second attempt. The flexible catheter is generally slender, and of sufficient length, and no stylet may be necessary in all occasions, and in all forms of the urethra. By having a stiff wire, we can give that wire, either before or after it has passed into the catheter, whatever shape we please; and what is of still greater importance, we can introduce the instrument without it

with the wire, in circumstances easy enough; or what is more advantageous, we can introduce the wire particularly so as not quite to reach the point of the catheter, but only to hold the two inches or a little more of that part, by which instrument the point of previously warmed and softened in the hand, has so much elasticity, that it follows the precise curve of the urethra, and yet has sufficient rigidity to overcome any slight resistance. If this fails, and especially if there be the slightest reason to suspect that the resistance is unusually excessive, but arises from stricture near the neck of the bladder in a young man, or swelling of the prostate in an old one, we may take a small bougie, turn up the extremity of it with the finger and thumb, so as to make a figure towards the penis, and allowing pressure for the wire to be softened, pass it quickly down to the stricture, turn it with a vertical or twisting motion, and make a gentle transverse part, withdrawing it to about ten minutes or a quarter of an hour, the same gently repeated, or the catheter may now be introduced.—(See *Sur's Principles of Surgery*, vol. 2, p. 355.)

Mr. Hey found, that of withdrawing the point of an elastic gum catheter, the instrument becomes more curved; and he treated himself to this operation, by withdrawing the style, so he introduced the catheter beyond the neck of the penis, by which action the point was raised in the due direction. He says, that may sometimes, though not always, succeed in introducing an elastic gum catheter, by using one which has acquired a considerable degree of curvature and firmness by having had a curved steel rod in it a long while. Introduce this within the urethra, with its convexity towards the abdomen, taking care not to push on the point of the instrument, after it has reached the sigmoides plicae, until its handle is depressed into a horizontal position.

When it is necessary to draw off the urine frequently, and the surgeon cannot attend often enough for this purpose, a catheter must be left in the urethra till an accident or the patient himself has treated the mode of introducing the instrument.

Mr. Hey inquires the formation of a false passage, or the rupture of the membranous part of the urethra, generally to the method of passing forwards the catheter before an abscess has been depressed. In this manner, the course of the instrument crosses that of the urethra, and the point of the catheter, pressing against the posterior side of the membranous part of the urethra, is easily forced through the coats of that canal. The word of this operation in the catheter, and of a false passage in its point, greatly contributes to facilitate the surgery. When it has now happened, the point of the instrument passes more readily into the wound, than along the urethra against the sigmoides plicae; and a great deal of skill is requisite to prevent this disadvantageous occurrence from repeatedly taking place, and rendering the case more and more serious.

Mr. Hey mentions a difficulty of this kind, by sending against the point of a silver catheter, so as to keep it more closely in contact with the anterior part of the urethra, and thereby pass into the wound made in the posterior side of the canal. In the instance alluded to, as it was necessary to leave an elastic gum catheter in the urethra, Mr. Hey proposed some means of a proper thickness, with which to make a strict, and having given it the same curvature as that of the silver catheter, he introduced it about four hours after the preceding operation, and fixed it by tying it to a ringlet. Mr. Hey sometimes succeeded by partly withdrawing the style at the moment when he wished to increase the curvature of the catheter.

In an instance in which the urethra had suffered a violent contusion, Mr. Hey drew off the urine with a silver catheter of unusual thickness, after he had fitted with instruments of a similar form. He suspected that the urethra was ruptured, and was obliged to raise the point of the catheter by a finger introduced into the vagina, and to use bleeding, purgatives, two or three grains, and often before it could be made to pass. The elastic gum catheter was after used employed. It was as quartered point, whether it is best to leave the catheter in the urethra until the power expelling the urine is revived, or to draw off the urine twice a day, and withdraw the catheter after each evacuation. Mr. Hey thinks that a general rule can be laid down; namely, to leave the catheter in the urethra to remain introduced;

others seem to suffer no inconvenience from it. On the whole, however, Mr. Hey commonly prefers removing the catheter. In this manner, he is of opinion, that the power of expelling the urine again is sooner acquired.

The preceding question is often determined by the nature of the disease, and as Mr. Hunter observes, in cases of *stricture* of the bladder, and where a catheter passes with difficulty, or with great inconvenience, as well as in other instances in which it must be used frequently and for a length of time, it will be necessary to keep it introduced, so as to leave the water to pass freely through it.—(On the *Stricture Disease*, vol. 2, p. 131.)

In France, a crystal silver catheter (*probe opaque*) is frequently employed in difficult cases by Boer, Roux, &c. This instrument has a very slight curvature, and an extremely smooth point. By force, regularly applied, it is introduced into the bladder in spite of all opposition. Care is taken to keep it in the centre of the passage, and the direction of its point is judged of by the position of the lateral angle. The tube introduced by Boer, for counteracting the great depression of the outer extremity of the instrument is taken, by the difference in the texture, the point can be seen to have reached the apex of the prostate.—(See *Stricture of the Bladder, Addressed at Paris*, by J. Cruveilhier, p. 118.) In bad cases the crystal catheter is usually allowed to remain introduced three or four days, and on being withdrawn, a small flexible gum catheter generally admits of being used.

The double manner in which the French surgeons employ the crystal silver catheter, seems often to give well-informed observers. Thus, in two examples, which were mentioned and examined by Roux himself after the disease of the prostate, a false passage had been made, no flexible gum catheter could be passed, the urine was effused in the cellular membrane, and the parts were gangrenous.—(See p. 116 of the above work.) According to the observation of Mr. Cruveilhier, the French surgeons employ the crystal silver catheter with too little discrimination, and "in their practice they seem to make no new distinctions between impediments to the flow of urine from the bladder, and adhesion and suppuration of the prostate gland, and suppurative structure of long duration. If the crystal catheter be introduced at all, it is in the last of these cases, particularly when combined with female stricture; and none of the surgeons who are familiar with the treatment of diseases of the urethra, occasionally are aware which approach very closely to the forcing method of the French. I have heard of instances, in which John Hunter employed great force both the silver catheter, and against the obstruction. I have seen Mr. Pearson (who generally treats catheters as rigid), and I need hardly say, as occasionally as any means take a shock, and push it gradually and forcibly on into the bladder, at the same time forcing his way, as it were, by keeping one finger in the rectum: the relief of the patient, and the ultimate cure of the disease, were the results of this practice."—(P. 118.) It appears further, that the crystal silver catheter has been used by M. A. Cooper. Whether altogether considering the conventional employment of this instrument, I perfectly coincide with Mr. Cruveilhier, that it is one with which young men, of little candour and no experience, may do more harm in the first few cases they meet with, than the rest of their life will afford them opportunities of doing good.

Mr. Hunter refers to instances in which the common catheter had been pushed through the preputial part of the prostate gland into the bladder, and the water then drawn off; but, "in one patient the blood from the wound passed into the bladder, and increased the quantity of matter in it. The use of the catheter was stopped a second time; but not succeeding, I was sent for. I passed the catheter into it again to a stop, and then suspecting that the part of the prostate projected forwards, I introduced my finger into the stricture and laid that gland very nicely exposed. By depressing the handle of the catheter, which of course raised the point, it passed over the projection; but unfortunately, the blood that was in the bladder, which filled up the hole in the catheter, so that I was obliged to withdraw it, and clear it repeatedly. This I repeated several days; but suspecting that the coagulum about it the end kill, I stopped cutting the

Mixed surfaces, in order to maintain a discharge. The cerium salina, however, which answers much better, and is not attended with danger of drying or straggling, inflammation of the eyelid, &c., has almost superseded the cerium cartharidis.

CERATUM CETACEUM. (L.) The spermated cerate. A mild, emollient, saline for ceration purposes.

CERATUM CONDI. (L.) *Ceratium conditum* (L.) (See *Emplastum*.) *Ceratium* (L.) *Ceratium* (L.) (L.) One of the salines at St. Bartholomew's Hospital, occasionally applied to cancerous, scrofulous, and phlegmatic sores.

CERATUM HYDRARGYRI SUBMURIATIS. (L.) *Hydrarg. submurat.* (L.) Cerate liquid, submuriat. (See *Mercur. praeparationes* are partial to this as a dressing for chancre.

CERATUM PLUMBI ACETATIS. (L.) A mild, emollient, neutralizing salve.

CERATUM PLUMBI COMPOSITUM. (L.) An excellent gently antiseptic salve for ceration purposes.

CERATUM SAPHNE. (L.) *Sabine foliorum extractum confusum* (L.) Cerate liquid, saphne. (See *Preparationes*, &c.) Mix the sassa with the sassafras and the sassafras, and strain the composition.

The cerate application for keeping open blisters, on the skin recommended by Mr. Crockett—(See *Blister*.)

CERATUM SAPONIS. (L.) *Ceratium saponis* (L.) Cerate liquid, saponis. (See *Preparationes*, &c.) Mix the sassa with the sassafras and the sassafras, and strain the composition.

The way of ceration at St. Bartholomew's Hospital, in preparing it, the cerate cerate must be used. The first three ingredients are to be mixed together and boiled gently till all the moisture is evaporated; after which the wax and oil, previously melted together, must be added. The whole composition, from first to last, must be incessantly and continually stirred, without which the wax will be spoiled. This formula was introduced into practice by Mr. Dorr, and is found to be a very convenient application for ceration and ceration, being of a mild, emollient, neutralizing degree of alkalinity, and at the same time possessing the usual properties of a cerate cerate.

In applying that cerate, spread it level, in thickness of the leg or arm, or whatever is necessary to be observed, namely, that it be in two distinct pieces; for if, in one piece, the skin is encircled by it, and the ends overlap each other, it will leave a very inconvenient and partial constriction of the fractured part, in consequence of the subsequent contraction. (See *Pharm. Chirurg.*)

CERUMEN ALBID. A degree of leanness is frequently produced by the indigestion of hard dry pellets of this substance in the nostrils and nostrils. The best plan, in such cases, is to sponge the ear with warm water, which should be repeated with moderate force.

In some instances, leanness seems to depend on a defective secretion of the cerumen, and a consequent dryness of the nostrils. Here, a drop or two of almond oil may now and then be introduced into the ear, and frequently applied.

CERUMEN ALBID. A degree of leanness is frequently produced by the indigestion of hard dry pellets of this substance in the nostrils and nostrils. The best plan, in such cases, is to sponge the ear with warm water, which should be repeated with moderate force.

CHAMÆLEON. (From *chama*, a lizard, and *leon*, a lion.) A lizard, the habits of the lizard, which has been historically supposed to resemble a lizard. When the lizard is in the sun, it does not creep, but changes into a hard, fleshy mass, it receives the application. (See *Medicinal*.)

CHAMÆLEON. The flowers, which are finer and aromatic, are used as surgery for making emollients.

CHANCER. (From *chama*, a lizard, and *leon*, a lion.) A sore which arises from the direct application of the venereal poison to any part of the body. All sores of this kind are called chancres. Each venereal sore is made out from a general contamination of the system, in consequence of absorption, never have the same chance applied to them. It is in accordance of the nature and treatment of chancres, see *Venereal Diseases*.

CHENOPHIL. (From *chama*, a lizard, and *leon*, a lion.) A lizard, the habits of the lizard, which has been historically supposed to resemble a lizard. When the lizard is in the sun, it does not creep, but changes into a hard, fleshy mass, it receives the application. (See *Medicinal*.)

lent, it frequently happens, that lymph or blood is effused in the cellular membrane, which connects the cornea with the anterior lamellae of the eye, hence, the latter membrane is gradually elevated upon the eyeball, and projects towards the eye, so as to conceal within it the cornea, which appears as if it were depressed. In this way the middle of the eye assumes the appearance of a gap or aperture.

It is observed by Mr. B. Wilson, that if temporary chancres are generally dependent on the lymph swelling of the venous fibres, but that it may also partly arise from effusion. He notices a very firm, but pale, chancrous, as occasionally produced by effusion, and resembling a solid ulcer, or fist. In one case of this sort which fell under his own observation, there were numerous white spots on the venous surface. (See *Prick on Diseases of the Eye*, note, p. 12.)

The time has arrived when surgeons had faith in the application of the vapour of ether, or of an ignited decoction of the sweetened acids, to an inflamed eye, for the relief of chancres, as recommended by the late Mr. Ware. In this kind of case, more benefit will result from general treatment than from any local treatment. I have particularly relied on the salutary system of Mr. Ware, in certain chancrous cases, like first species of Mr. Wilson, topical remedies may be advantageously resorted to.

Acute ophthalmia, attended with chancres, demands the most vigorous employment of the antiseptic treatment. Both general and topical bleeding should frequently and copiously put in practice, with the required, however, to the age and strength of the patient. Leeches should be applied to the vicinity of the eyelid; or, what is preferable, the frequent use should be resorted to. When chancres are very considerable, Scarpa's method of making an incision in the conjunctiva, near its junction with the cornea, for the discharge of the lymph or blood lodged under the diseased membrane. (See *Ophthalmia*.)

CHIRASTIC. or *Chirastica*. A double-headed roller, the middle of which was applied to the chin; the bandage then crossed at the top of the head, and passed on each side to the nape of the neck, where it crossed again. It was then carried up to the top of the head, and so on, till all the roller was exhausted.

CHIRASTIC. A bandage for stopping haemorrhage from the temporal artery. It is double-headed, about an inch and a half wide, and four feet long. Its middle is applied to the opposite side of the head; the bandage is carried round to the bleeding temple, and there made to cross over a compress on the wound. The roller is then extended over the coronal suture, and under the chin, care being taken to make the bandage cross upon the compress. In this way, the rest of it is applied round the head.

CHILBLAINS are the effect of inflammation arising from cold. A chilblain, in its mildest form, is attended with a moderate redness of the skin, a sensation of heat and itching, and some or less swelling, which disappears, after a time, spontaneously disappears. The inflammation changes and sense of tingling, accompanying the inflammation of the middle description of chilblains, are observed to be frequently aggravated by exposure to heat. In a more violent degree, the swelling is larger, redder, and sometimes of a dark blue colour; and the heat, itching and pain are so excessive, that the patient cannot use the part. In the third degree, small vesicles arise upon the tissue, which burst and leave excoriations. These often change into ill-conditioned sores, which sometimes penetrate even as deep as the bone, discharge a thin ichorous matter, and finally prove very obstinate. As Dr. John Thomson has remarked, "when the serum contained in the vesicles is let out by a small opening, a portion of new granule is usually formed to supply the place of that which has been separated; but when the inflammation is violent, and the affection neglected, or improperly treated, the parts which are the seat of venous are liable to pass into the state of venous ulcers. In this state, they yield to the chancrous or scrofulous discharge, and are generally healed, only after a long time, and with great difficulty, to a healthy appearance. In neglected cases, these ulcers not infrequently become covered with fish sloughs. Ulcers often supervene, and the soft parts covering the bones are destroyed." (On Inflammation, p. 63.) The worst stage of chilblains is attended with sloughing.

thickness of the granules. When granulations are formed upon a fixed surface, their contraction is mechanically impeded; as, for instance, on the skin, the hair, &c. Hence, in all instances on such parts, as much skin should be saved as possible.

The shape of a sore, as well as its situation, makes also a considerable difference in its granulations: first, as Mr. Askey (who has remarked, a sore of a circular form, extends peripherally, till it ceases to granulate, then another of a more elongated form has less diameter.—*Forrest*, vol. i, p. 223.)

When there has been a loss of substance, making a hollow sore, and the contraction of the granulations has begun, and made a good deal of progress, before they have had time to rise as high as the skin, then the edges of the skin are gradually drawn down, and turned as it is in the hollow direction of the surface of the sore.

The contraction of the granulations continues till the healing is complete; but it is greatest at first. Then there is a mechanical resistance to contraction, is proved by the assistance which must be given to the process by the application of a bandage.

Second, the contractile power of the granulations, there is a certain power of the surrounding edges of the granulating skin, which resists the contraction of the granulations, and is generally more considerable than that of the granulations themselves, drawing the mouth of the wound together like a purse. The contractile power of the skin is confined principally to the very edge where it is contracting, and, as Hunter believed, to two very granulations, which have a ready resistance, for the nature of organic skin surrounding this part does not contract, or at least not nearly so much, as appears by its having been drawn out folds and flaps, while the new skin is smooth and elastic.

The form of the contraction of granulations are various. It is evident, the healing of a sore, at there are two openings, going on at the same time, the contraction will proceed.

It avoids the formation of marks on skin, the advantages of which is evident: for it is with the skin as with all other parts of the body, viz. that such as are originally formed are much more fit for the purpose of life than those which are newly formed, and not nearly so liable to absorption.

When the whole surface of a sore has skinned over, the secondary, the remains of the granulations on which the new skin is formed, still continue to contract, till hardly any thing more is left than what the new skin would hold. This is a very small part, in comparison with the first formed granulations, and it is in time looks most of its original vessels, becoming white and ligamentous. All newly healed sores are at first redder than the common skin, but in time they become much whiter.

As the granulations contract, the surrounding old skin is stretched to cover the part which is deprived of skin.

When a sore begins to heal, the surrounding old skin, close to the granulations, becomes smooth, and round with a white cast, as if covered with something white. Thus, Mr. Hunter supposed to be a healing cuticle, and it is as soft and more a symptom of healing as any. While the sore retains its red edge all round, for awhile a quarter of half an inch is healed, we may be certain that it is not in a healing state.

Skin is a very different substance, with respect to texture, from the granulations upon which it is formed; but it is not known whether it is a new substance formed by the granulations or a change in the surface of the granulations themselves.

The new skin then constantly takes its rise from the surrounding old skin, as if it flowed from it; but, according to Mr. Hunter's theory. It is very long before the principle of skin, in which the edges of the surrounding old skin had little tendency to contract, and the cellular membrane underneath is rigid, or the old skin is become drawn over the granulated surface, the granulations do not appear a contracting disposition. In such cases, new skin forms in different parts of the floor, making up the surface of the granulations like little islands.

This power of the nature of a sore to form new skin, however, is not universally allowed; and while Mr. Askey Cooper acknowledges the fact of increased secretion of skin being sometimes seen in the middle of

sores, nevertheless, this such appearance is produced in consequence of the whole of the skin not having been destroyed by absorption, and granulations having arisen from the part of the skin which was left. Thus, he says, and I suppose to irregularly formed sores, where, after the healing process has gone on to the centre, the new breaks out again at the circumference.—(*See Lancet*, vol. i, p. 223.)

Whatever change the granulations undergo to form new skin, they are generally guided to it by the surrounding skin, which gives this disposition, in the surface of the adjoining granulations.

The new-formed skin is never so large as the skin was on which it is formed, owing to the contraction of the granulations, and the yielding of the surrounding skin. If the sore is situated where the adjoining skin is loose, as in the scrotum, then the contractile power of the granulations being quite lost from obstruction, a very little new skin is formed; but if the sore is situated where the skin is held at tense, the new skin is nearly as large as the sore.

The new skin is at first continuous on the same level with the old. This, however, is not the case with sores and ulcers, which frequently heal with a cicatrix higher than the skin, although the granulations may have been high from rising higher than this part.

The new-formed skin is either as yielding not so elastic as the original; or it is also less movable. It gradually becomes, however, more flexible and loose. At first it is very thin and tender, but it afterwards becomes firmer and thicker. It is a smooth continued skin, not formed with those irregular undulations which are observed in the natural or original skin, and by which the latter admits of any distension which the cellular membrane itself will allow of.

The new skin, and indeed all the substance which had formerly been granulations, is not nearly so strong, as the originally formed parts. The living principle itself is less active; for when an old sore breaks out, it continues to yield, till almost the whole of the new-formed matter has been absorbed, or has exfoliated.

The young skin is extremely full of vessels; but they afterwards disappear, and the part becomes white. Hence the white appearance of the cicatrices or marks of granulation.

The surrounding old skin being drawn towards the centre by the contraction of the granulations, it then has loose folds, while the new skin itself seems to be open the stretch, having a smooth shining appearance.

The new cicatrix is more easily formed than the skin, than the skin itself from granulations. Every part of the surface of the skin is concerned in forming cuticle, so that not a forming equally over where it does; but the formation of the cuticle is principally, if not entirely, progressive from the adjoining skin.

The new cicatrix is at first very thin, and rather pulpy than leathery. As it becomes stronger, it looks smooth and shining, and is more transparent than the old cuticle.

The rate of progress is later in forming than the cuticle, and in some cases never forms at all. In blacks, who have been regarded as slow, the cicatrix is a considerable time before it becomes dark; and in one black whom Mr. Hunter saw, the cure of a sore, which had been upon the leg when young, remained white when he was old. This case, however, must have been an unusual one; for it is now mentioned that the new skin of a negro does not become white, but is at first red, and after a time turns blacker than the original skin.—(*See A. Cooper, Lancet*, vol. i, p. 227.)

According to this gentleman's observations, tendons and cartilage are the only parts of the body incapable of being regenerated in the process of cicatrization; when a tendon is divided, it unites by means of a firm dense substance; and, except in very young subjects, the cartilages of the ribs irreparably unite with the intervening bone.—(*Hunter, On the Blood, Inflammation, &c. Philosophical Lectures on Inflammation*, p. 248, 249.)

CICUTIA. See *Cactus* *Reichenow*.

CINCENSA. An one of the designs of this Dictionary is to explain the subjects of a varied phenomena, Peruvian bark, which is administered in a very great number of various cases, seemed to present only in effect.

The first regard for its action in stopping vomiting

them, and recommending the rejection of the stomach, every person, whether of the medical profession or not, has frequently heard of. Indeed, so high is the character of this medicine, that many practitioners, before it is so much as a matter of almost every disease, often prescribe it when it is totally useless, give it when it actually does harm, and make their patients swallow such quantities as create perturbation, when smaller doses would effect striking benefit. Some men are credulous enough to think, that from the Tonic bark's vigor and strength are directly connected and inferred the constitution, in most proportion to the quantity of the medicine which the stomach will keep down and digest.

With a decline of this sort, perhaps, we must expect to see infirmities and symptoms practice. The quantity of disease will always be attended with an expenditure of language and weakness, and certainly, while there exists a supposition that a drug is of benefit, procuring the quality of evoking and maintaining strength, it would be absurd to fancy that so important an article will not be highly exhausted in a multiplicity of medical cases. I need not presume to furnish an idea of the power of the Tonic bark in the practice of physic; but I have not the least doubt that they have been unwarrantably compressed in surgery, as in a kind and prolixo space, a continuance of good diet, and local ties to adopt, together with simple methods of treatment.

Under peculiar circumstances, bark has undoubtedly the quality of increasing the tone of the digestive organs; and, of course, whenever the indication is to strengthen the system by stimulating food, and the appetite fails, this medicine may prove of the highest utility, provided it be given in moderate doses, and if it be found to agree with the stomach and bowels. For the plan of making the patient swallow as much of it as can be got into his stomach, even, in my opinion, he inevitably followed by bad instead of good effects. How can it be reasonably expected that the stomach, which is already out of order, can be so right by taking an immoderate quantity of any drug whatever forced into it? In fact, if the alimentary canal were in a healthy state, would not such practice be likely to throw it into a disordered condition?

Bark is an excellent medicine when judiciously administered; but, like every other good medicine it has faults, it may be the means of producing the worst consequences. How much good does every effort to eradicate tumors of surgical disease, when prevented by a surplus of emaciation; what a poison it becomes under the direction of an ignorant practitioner! With respect to cases of indigestion, bark is often most strongly indicated when the vomiting is not accompanied with active inflammation, when the patient is debilitated, and his stomach cannot take nourishment. I have always regarded the notion of giving bark as a specific for gastritis as totally unfounded and absurd. I have witnessed its effects in these cases, but could never discern that it had the least peculiar power of operating directly upon the parts which are diseased. Whatever good it does is by the improving the tone of the digestive organs, and making them more capable of carrying nourishment, and of course through into the circulation.

I should feel myself guilty of a degree of partiality in speaking thus freely upon this subject, were not my sentiments in some measure supported by those of foreign celebrated writers, the remembrance of whom will always be aided with undigested veneration and esteem. Mr. Samuel Hahnemann has not hesitated to bark, and while he allowed it to possess a share of efficacy, he would not admit that it was capable of miraculously dissipating every disease which the stomach is prejudicially affected. "I know," says he, "it will be looked upon by many as a kind of sleepism, to doubt the efficacy of a remedy so well attested by even an infirmity of taste; and yet I shall frankly own I have never clearly to my knowledge met with any evident proofs of its preference in the medical indication merely prescribable though I have a long time made experiment of it with a view to search into the truth.

Perhaps it may seem strange then to suppose a doctrine established on what is called matter of fact; but I shall have observed that in the practice of physic and surgery it is often exceedingly difficult to ascertain a fact. Prejudice or other obstacles sometimes pre-

clude us from judgment, where there is evidently a right and a wrong; but in certain cases so distinguished from the remedy and how the nature operates, is probably above our discernment. In gastritis particularly, there is frequently such a combination of an known circumstances as cannot but lead to diverse an erroneous observer. Modifications arising from cold, compression, or structure, particularly in relation to the veins, and are therefore, many other causes for proving the power of the bark. However, there are two kinds of gastritis where cinchona has a superlative; these are a spreading gastritis from a violent cause, and a spreading gastritis from violent external causes, such as great cold, wounds, contusions, &c. Yet even here we cannot judge of their effect with absolute certainty; for sometimes a healthful reaction from several causes is a kind of critical disorder. These seems to be a certain portion of the body detaching period, and in some, of the way as a result of various things brought into our system. While the gastritis stops at a tolerable point without the least assistance from it. The same thing happens in the acute species of gastritis from cold, or cold, where the injury appears to be exaggerated to a certain distance and so forth; though, to the way, I shall remain in this place, contrary to the received opinion, that gastritis from these causes (where there has been no previous stricture of the vessels) are within reach as these from internal causes.

As I have here stated the bark, we now have difficult it is to ascertain the real efficacy of this medicine; but bark in any degree does wonderful effects in gastritis. While it has its peculiar indications, its preponderance would be more to be decided in the case than in the other. What, in my judgment, seems to have raised its character as high, are the great number of simple observations published on the subject, the others of which, not having frequent opportunities of seeing the facts of this disorder under the use of cinchona, &c., and some of these, perhaps, produced by the common supposition, that every gastritis is an inflamed state, have therefore excited a universal infatuation to the bark, when the crime has proved successful. (Sherris's first, second, &c. on Gastritis.)

Some further remarks on this subject will be received by the article Morphology.

According to Mr. Brissot, bark is a specific for old ulcers, where the inflammation seems concentrated at the bottom of an inch round the sore, the surface of the bottom looks glossy, and the discharge is constant thin and very odorous, with little or no sleep than the violence of the pain. The further advanced, the the addition of opium, or sometimes only opium, will often be found necessary. (Chirurgical Observations and Cases, vol. 1, p. 124.)

Bark is given so extensively in the practice of surgery, that there are few important cases in which it is certain circumstances, and administered in another, are not indicated. When persons have been weakened by a cerebral hemorrhage, or by the effects of any disease whatsoever, moderate doses of bark will frequently be found of great service. But it only becomes when the gastritis arises suggested, and as far as my judgment extends, this medicine should never be prescribed in any surgical cases in excessive and unattended quantities.

The use of cinchona in combination with one-fourth part of potassium or soda, is found of essential service as a tonic in the debility and constitutional irritation which are induced in some patients by the excessive use of mercury, and I learn from my friend Dr. Francis, that he has recently tested its efficacy in the same manner. In the mercurial sore-throat of long standing, it has proved an effective remedy, and as the use will be alleviated or combated with heat and other remedies in building the indications required in the same preparation. — *Done.*

The yellow bark, or the *assa cinchona cordifolia* of the botanists, is said to possess nearly equally the same pharmacopoeia, as to the general nature of the compound preparation of the species described, that the effects of the various kinds of cinchona make it an infallible tonic, or alkaline elements, instead of alkaline, and moreover, in that of being able to preserve the properties which will concentrate all the efficacy of the medicine in formulae of moderate bark, not likely at least to disorder the alimentary canal by the medicinal effects of quantity.

COLPOPTOSIS. (From *collo*, the vagina, and *ptosis*, to fall down.) A lowering or falling down of the vagina. (See *Vagina*, *Protrusion of*.)

COMMUNITED. (From *communis*, to break in pieces.) A fracture is termed comminuted when the bone is broken into several pieces.

CONJUGES. (From *conjugere*, to press upon.) Food, hairs, lint, or other materials, entering a sort of pad, which occupies place near those parts of the body on which they wish to make particular pressure; and for this purpose a bandage is usually applied over the conjuges. Conjuges are also frequently applied to promote all efforts which the pressure of hand but in a light language would otherwise diminish.

COMPRESSION OF THE BRAIN. See *Brain*, *Injuries of*.

CONJUNCTION OF THE EYES. See *Eye*, *Injuries of*.

CONDYLOMA. (From *condyla*, a tubercle or knot.) A small, very hard tumour. The tumor is generally applied to cancerousness of the description about the anus. The practitioners may either destroy them with caustic, or, if they have with a ligature, or remove them all at once with a knife; the first is generally the most, the last the best and most speedy method.

CONIUM MACULATUM. Hemlock. (Latin.) This is a medicine to which the observations in practice incident to so large a considerable efficacy in several surgical diseases. However, there is no doubt, that when it is represented as a certain cure for cancer and scirrhus, exaggeration is employed. It is an extremely ready for curable painful sort of the scirrhus kind, and it will dissipate the cure of many others in which the cancerous matter has been destroyed by surgery, though the healing does not proceed in a figurative way. However, in medicine hemlock is several scirrhus malignum, scirrhus, particularly cancer which are every now and then met with upon the tongue. It is an slightly alterative in cases of cold in the tongue, portage, and various hepatic affections. It has several several components of the female form give way to hemlock, combined with calomel. Some swellings of the female (as the) is the more common. However, certainly has not the power of curing cancer; but its narcotic properties tend to remove the pain of that disease, so as to render it by no means a considerable remedy in the treatment of that case.

Regarding hemlock, Dr. Parrish observes, that the extract and powder may be extremely given with evidently good effect in several irritable cases, whether they are connected with the active state of the venereal virus, or whether they remain after the completion of the venereal course; and a small dose, that the benefit conferred by the drug ought not to be ascribed solely to its venereal qualities, since diseases attended with cancer always be obtained by the direct exhibition of opium, even where it does not disagree with the stomach. He states that opium is almost a specific in the venereal ulcers which attack the corn at the end of the penis. With this fact and many frequently become gleet. Also, in venereal sores which are accompanied with great pain, and no appearance of considerable healing, hemlock will often remove that hurt, either, or calomel. The common mode of exhibiting hemlock is in the form of pills, made of the tartarous root, five grains in each. However, I have often thought three grains sufficient to begin with the dose being afterwards gradually increased, till several new large quantities may at last be taken at one time. Dr. L. Wilson, in his *Pharmacopoeia Therapeutica*, advises what a remarkable case of cancerous ulcers, for which the patient took a hundred and twenty pills, each consisting of five grains of the extractum, in twenty-four hours, and thus without any benefit being obtained, or any improvement in the patient.

The patient being a little disordered, and the head somewhat full, is a sign of the dose being sufficiently strong.

According to some writers, but more particularly Dr. Whistler, there are severe stages in which the virus of a venereal practitioner, in presenting this remedy, may be frustrated. The plan chosen for purging the system may not be the free evacuation of the blood, which is indispensable for the cure of the disease. It only not be suffered when in perfection, and it may be suffered when in perfection. The practitioner

of the cure may not have been performed in a temperate way, for the sake of blood, over a venereal disease. The course, of which the powder is made, may not have been carefully dried and preserved in a well-stopped bottle, or, if so, may still have been guarded from the effects of exposure to light. In both, the whole medicine may have suffered from the mere effects of long keeping. From any of these causes, it is evident, the proposed remedy may have suffered, and it happens, we could, very frequently, that the failure of it might, in fact, be attributed to one, or other of them. (See *Mercurius* *Chlorureus*, published in 1812, p. 174.)

The utility of hemlock is now found to reside in a resinous element, obtained separately by reprecipitating an ethereal tincture of the leaves on the surface of water. A dose of half a grain will produce warmth and headache. The watery extract of this plant has been proved by Orfila to have little power. (See *J. A. Paris*, in *Pharmacologia*, vol. 2, p. 181, col. 9.)

I have sometimes prescribed, as an alternative, with excellent benefit in several surgical diseases, a pill containing three grains of extractum conii, or, what is preferable, the dried leaves, one of hydragric substances (calomel), and one of antiscorbutic substances (vitellus). In various cases of scirrhus cancerous, and also in several very painful irritable ulcers and abscesses, it is occasionally employed in the form of hemlock in various positions. The leaves are generally made by mixing the powder with the common bread and water cataplasms. *P. Hoffman*, of Hemlock, has found, that *A. Struth*, *Leibnitz*, and *Democritus* examine an extract and extractum cataplasms, and of various remedies with little, or no effect, others, few, *Virchow* 1861. Also, *Supplementum Pharmacopoeiae de Conio*, by *Virchow*, 1861. *J. Pearson*, in the *Various Articles of the Materia Medica*, *de Med. Res. London*, 1867. *J. A. Paris*, *Pharmacologia*, vol. 6.

CONJUNCTIVA, GRANULAR. The following account of this subject is given by Dr. Frick. The disease is mostly the sequel of venereal syphilis. It is characterized by a rough, swollen, or granulated state of the palpebral conjunctiva, with a glossy or purulent discharge from its surface. The constant friction of the eyelids upon the globe brings on a various state of the venereal conjunctiva, and a daily appearance of the venereal. The patient complains of a sensation similar to that produced by sand, or other extraneous matter, under the eyelids, the eye cannot endure the light, and there is a troublesome epiphora. In the early stages, a cure is easily accomplished by the application of a few leeches to the eyelids, and purging the patient once or twice a day with the common tincture of opium, or the ergot of rye, &c. When these means fail, the sulphate of copper or nitrate of silver may be used, though not so freely as to produce a slough, but only to destroy the diseased condition of the part. (See *Frick*, *the Flow of the Eye*, p. 188, vol. 2.) Mr. H. Walbank recommends the use of these means to be followed by abstinence with tepid water, and the application of a few leeches. He also recommends counter-irritation and antiseptic. The upper eyelid, he says, should be completely everted in examination, as there is sometimes, in the angle where the conjunctiva passes from the globe to the lid, a crescentic, bluish fold, he called a cock's comb, not taking up a distinct, white, shining state of the cornea. Dr. Frick considers removal of the granular surface proper only when it is hard, insoluble, and persistent, or the excoriation being the progress from the surface of the eyelids. In this state, Dr. Virchow recommends the application of a little tincture of iodine, and then washing it off with a sponge. (See the article *Gonorrhea*, and *Frick*, *Treatise on Diseases of the Eye*.)

EXTENDED WOUNDS. See *Wounds*.

CONTUSION. (From *contundere*, to bruise.) A bruise. A slight bruise seldom meets with much attention; but when they are severe, very bad consequences may ensue; and these are the more likely to occur, when such cases are not taken proper care of.

In all severe bruises, besides the inflammation which the violence necessarily occasions, there is an extraordinary effusion, in consequence of the rupture of many of the vessels of the part. It is not that very few we account for these very considerable tumours, which often rise immediately after injuries of this nature. The black and blue appearance (initially following many bruises) can only be explained by some thing

It is observed, that a simple incision through the varicose vessels is not permanently efficient in destroying all direct communications between the crura and plexiformities of these vessels upon the ovum, after such an incision made, the discharge, with a hæmorrhage, it is true that a separation of the vessels of the divided vessels follows in opposite directions, it is no less true, that in the course of a few days afterwards, the mouths of the same vessels approximate each other, and reunite, so as to restore their former continuity. Hence, to derive from this operation all possible advantage, it is essential to extirpate with the knife a small portion of the varicose phloids, together with the adherent portion of the tunica connectiva.

The vessels are to be separated from the uterine artery by a skilled assistant, who is, at the same moment, to support the patient's head upon his breast. The surgeon is then to take hold of the vascular vessels with a pair of small forceps, near the edge of the uterus, and to lift them a little up, which the lax state of the surrounding tendons may; then, with a pair of stout, curved scissors, he is to cut away the pieces of tunica vaginalis, together with a small piece of the mesometrium, making the vessel of a scissor-like form, and as near as possible to the uterus. If it should be necessary to operate upon more than one placenta or uterine vessels, situated at some distance apart, the surgeon must elevate them one after the other with the forceps, and remove them. After which they are very close together, and occupy every one of the exp. In most cases, an undivided circular incision in the vagina, making it nearly to the margin of the external os, and so as to divide with the scissars all the uterine vessels.

This being done, he must allow the cat to come to blood freely, even passageway, the hemorrhage by loosening the eyelids, until the blood discharges in flow. Scarify then cover the eye with an oval piece of the compressing sponge and a restorative liniment. The eye ought not to be opened till twenty-four hours after the operation, when, usually, the agency of the vessels will be found completely obliterated; and, during the ensuing days, the patient is to be enjoined to keep the eye wet, and covered with a bit of fine rag. A collyrium of milk and rose-water, warm, may be applied two or three times a day. When the inflammation of the conjunctiva happens, about the second or third day after the operation, particularly is rare in which the lesions is made all round, while the greater part of the upper of the eye remains, a slight circle, in the place of the incision, forms a line of boundary in the redness which does not extend farther upon the cornea. This inflammation of the conjunctiva, with the aid of internal ophthalmologic remedies and topical remedies, abates in a few days, and then pus is secreted along the track of the incision in the conjunctiva. The wound contracts, and, growing smaller and smaller, soon cures. Raising the eye with warm milk and rose-water is the only local treatment necessary in this stage of the cure.

Thus, not only the first journey of the poem is improved, but also the prestructural fixity of the country is dissolved, or even removed. When the conformation subsequently appears relaxed and wrinkled, in the use of typical adjectives and metaphors, and of Latin's ophthalmic castigation, may be easily identified a preceding the occurrence of the viscous state of the poem. — (Karl's public *Madellé* shall think — N.Y.)

According to the representative of Dr. Vesseli, Bulgaria's chief of removing the poisons of carcinoma venodis, together with a portion of the accompanying, produces no good effect. "Symptoms of cancer of breast enlargement of the metastases involving the eye." He believes, that some women's extraordinary response to the toxin of those removed, and the good blessed from the bleeding does not correspond to the irritation produced by the operation—(A Practical Treatise on the Haematuria of the Eye p. 80.) However, whilst it is reflected, that surgery of this practice only for advanced cases, and particularly metastases beyond retrograde for the advanced stages of the disease, he heartily agrees with the report, as far as that point is concerned. The European movement of the disease and its treatment is left unaltered by the outbreak of any notion of the children repeatedly existing between dignity of the disease, and

eyelids. Yet, perhaps, *desmops* was not to be exposed in view of this condition in his chapter on *desmops*, because his definition of this superficial opacity will not altogether suit the affection of the same name as referred to in the following observations. It is marked by Dr. Vetch, that after the complete closure of conjunctival *desmops*, as far as regards that portion of the membrane which covers the eye, the villosity, elongation of the vessels of the lining of the eyelids, instead of moving, their natural state, acquire a farther interval of size, so as to produce a rough, scaly, or granulated surface, with a secretion of puriform mucus. The striation of this *desmops* variety gradually induces an indolent state of the sclerotic cornea, and, consequently, a greater flow of blood towards the cornea: the superficial vessels become varicose; the conjunctiva assumes a fleshy and blood appearance; and the cornea becomes opaque, not partially, but throughout the whole extent of its structure. This affection, says Dr. Vetch, is essentially different from those catarrhs or partial opacities which take place in primary sclerotic inflammation, and which consist in slight extravasations, accompanied by inflammation of light, and it is only very seldom that the purulent exudate is a necessary result of a primary inflammation. The cornea is of the green color presented by a broken glass pane, and while the sufficiently opaque cornea prevents the perception of light, it is just too opaque to allow the patient to discern external objects, except by their shadow. Nor can the outline of the iris and pupil of the eye be seen. Dr. Vetch also describes the conjunctiva as being sometimes so much relaxed, and its vessels so generally loaded, as to give it a fleshy appearance similar to that of the cornea; and, in other instances, without such alteration of its thickness or transparency, it is said to lose for a considerable extent its close adhesion to the marginal lamina of the eyelid. Along with the opaque state of the cornea, there is there generally an enlargement of several vessels, which produce almost to its centre, a disease as they were extrinsic, and separate in itself, which run to the disfigurement of the conjunctiva. Dr. Vetch represents the disease of the pupil as consisting at first in a highly villosity state of their membranous lining. This again, if not rectified by proper treatment, gives birth to granulations, which at first become more deeply situated, hard, or warty, accompanied by an itching or prurient matter. Dr. Vetch has explained, that the loss of the actual history, pressure, and friction, for the purpose of curing the diseased state of the eyelids, may be forced back in *desmops*, who prefers incisions. Dr. Vetch mentions his first employment in these cases to Dr. Ross. Mr. Saunders, he observes, took as early and a just view of the relations existing between the diseased condition of the palpebral fissure, and the opaque state of the iris; and he succeeded in establishing the cure of the latter by the removal of the former. In short, Dr. Vetch admits, that in the case which more especially served the aims of Mr. Saunders is the discovery of the nature of the disease, the practice of incisions was attended with complete success. Dr. Vetch contends, however, that this method is far the most part inadequate to the cure of the disease; and that there are very few cases, in which the more certain and constant process of gradually increasing the diseased surface by caustotic incisions will not produce a more speedy and permanent cure. After giving a fair and a plain variety of estimation made into certainty, and applied to the hands of the upper eyelid, Dr. Vetch found the direct application of the caustotic substances themselves was preferable. When there is too much increased action of the vessels of the conjunctiva, Dr. Vetch recommends the use of medicines to be provided by cupping the temples; or, when there is any risk of a slough, the application of a leech to the inside of the lower eyelid. Whatever will bring a determination of blood to the face is to be avoided, and a low regimen observed.

The exhortations, performed by Dr. Vach, are the outcome of deeper and truer faith, as, so called, the officers of peace and brotherly agreement. In his view, Dr. Vachya, they should be applied, not, as some have conceived, with the view of producing a wedge over the table together, but with great delivery, and in so many instances, as well produce a greater change in the minds, and disposition of the party. As long as there is one

secretion of tears, the above applications may be intelligibly assumed by the daily use of the opacified liquor glysteria extracta. When the disease remains these remedies, and its surface is hard and watery, Dr. Vetch applies to the corneal surface powder of verdigris or burnt alum, finely levigated, or even slightly touches the diseased lamellæ with the ball pen, in employing these remedies, he assumes removing their application to the point of contact, so as to prevent them from hurting the eye. Hence, they are to be applied in very minute quantities with a fine camel's hair pencil, and to be washed off with an elastic gum syringe, before the eye is returned. Of the employment of antiseptic collaria in conjunction with escharotics, Dr. Vetch disapproves.—(*Second Practical Treatise on the Diseases of the Eye*, p. 51, &c.). With respect to the treatment by escharotics, advised by Mr. Bealhouse with success, and afterwards by Mr. W. Adams with a knife, the principle of cure does not appear to me different from that aimed at with escharotics, unless those latter be supposed not always to destroy, but sometimes to cause an absorption of the fungus granulations. At present, the last method is considered most effectual, and during the operation the eyelids should be covered over a piece.

For the form of disease termed by Mr. Traverses—*aponeurotic*, with vessels protruding on the cornea, the prognosis is somewhat painful. He says, that "the hydropsyema (can corneæ or oedema), at small but frequent doses, will sometimes succeed better in this case, than the other forms of escharotics, and the combination of calomel with mercury, better than that with opium." When the internal exudation of mercury either destroys the lamellæ or has no effect on the cornea, blisters are to be performed.—(*Synopsis of the Diseases of the Eye*, p. 255.) In the particular form of opacity, to which he alludes, he disapproves of dividing the vessels of the lamellæ before the inflammation has subsided.—(p. 253.)

From some observations pronounced by Mr. Wardrop, it would appear, that certain quantities of the cornea are produced by an increase in the quantity of the contents of the eyeball, and not by the deposition of an extraneous fluid in the texture of the cornea, as takes place in the cataract opacities. He considers this fact proved, by cases in which the cornea regains its transparency the instant the aqueous humor was evacuated. Some cases are limited by this gentleman, with the view of recommending the practice of paracentesis corneæ, and discharging the aqueous humor, for the relief of the kind of opacity to which we have here alluded.—(*See Med. Clin. Transact.*, &c. p. 293, &c.)

For other opacity of the cornea, refer to *cataract*, *leucoma*, and *ophthalmia*.

ULCERS OF THE CORNEA.

An ulcer is a common consequence of the burning of a small abscess, which not infrequently forms beneath the delicate layer of the conjunctiva continued over the cornea, or in the very substance of the cornea itself, after violent ophthalmia. At other times, the ulcer is produced by the contact of caustic matter, or sharp pointed bodies introduced into the eye, such as metallic pieces of glass or iron, &c. As Dr. Vetch has observed, liberation of the cornea is a very frequent consequence of purulent ophthalmia. The little abscess of the cornea is attended with the same symptoms as the severe acute ophthalmia, especially with a troublesome sensation of burning at the eye, itching, and pain of the eye, with actual heat; a copious secretion of tears; aversion to light; a severe pain of the conjunctiva, particularly near the point of suppuration. The inflammatory process, compared with similar ones in any other part of the body, is more or less burning after matter is formed. Scarpa always it imagines, however, to produce the small abscess; for, though it assumes the appearance of being perfectly unattended, the matter contained in it is so tremendous and effusive to the substance of the cornea, that not a particle escapes out of the little abscess, and the second suppuration of the abscess, increases the opacity of the cornea, and often occasions another small abscess to form in the vicinity of the first. Indeed, if the observations of Mr. Traverses be correct, "the ulcer of the cornea, being not an abscess, but to a considerable degree of depth, is in pure inflammatory action."—(*Practical Treatise on the Diseases of the Eye*, p. 56.)

And Dr. Vetch takes notice, that the observation with respect to their matter never forming in the cornea, be invariably found true in several cases, where the whole of the eyeball had been diseased, where the whole of the eyeball had been diseased by inflammation.—(*Practical Treatise on the Diseases of the Eye*, p. 56.) This author differs from Scarpa, however, respecting the question of opening granules at abscesses of the cornea; for he remarks, that whenever the matter at depth is removed, the ulcer, however deep and extensive, will fill the vacant lamellæ being the consequence. If a little address, he says, it may in most instances be removed in a mass upon the point of a lancet or scalpel, &c.—(p. 56, p. 58.) This remark applies well to cases where lymph or mucous matter runs or less penetrates, and to instances in which it is quite confined between the lamellæ of the cornea. Scarpa thinks that the safest plan is to temper, and the possible spontaneously breaks, preventing it by means of frequent compresses, bathing the eye with warm milk and water, and applying constant pressure. The spontaneous bursting of the little abscess is usually denoted by a sudden increase of all the symptoms of ophthalmia; particularly by an insupportable burning pain at the point of the cornea, where the abscess first began, greatly increased by means of the eye eyelid. The event is confirmed by seeing the spot, and at the spot where the white matter appeared a cavity appears, as may best be seen when the eye is viewed in the profile. Extraneous bodies in the eye, which have simply divided a part of the cornea, or lodged in it, when soon extracted do not in general cause ulceration, as the injured part heals by the first intention. Those which destroy or burn the entire of the membrane, or which, when lodged, are not soon extracted, excite acute ophthalmia, suppuration in the injured part, and at length ulceration.

As Dr. Vetch has observed, the appearance of inflammation varies according to the degree of suppuration, or tendency towards it is the surrounding cornea; when this part is clear, the case is doing well, but when opacity comes to, the ulcer is increasing. The soft middle lamellæ, he says, is destroyed with great rapidity when the inflammation is violent, but as soon as the ulcer reaches the internal coat, it often proceeds no farther.—(*Practical Treatise on Diseases of the Eye*, p. 58.)

The ulcer of the cornea, as Scarpa remarks, has the appearance with all symptoms of ordinary in the skin, where this is delicate, tense, and endowed with exquisite sensibility, that at its first appearance, it is of a pale red color; that its edges lift and irregular; creates sharp pain; discharges, instead of pus at first water, and tends to spread widely and deeply. Such is the peculiar character of laceration upon the cornea, and such is the nature of those upon the tip of the tongue, the tip of the ear, the entrance of the meatus auditorius externus; nostrils, &c. Ulcers of this description, composed of ill-treated, speedily enlarge, make their way deeply, and destroy the parts in which they are situated. If they spread superficially upon the cornea, the transparency of the membrane is destroyed; if they proceed deeply and penetrate the anterior chamber of the aqueous humor, this fluid escapes, and a fungus of the human eye exists; and if it should form a larger opening in it, because the exit of the aqueous humor is so much more grievous probably than the above risk, namely, a prolapsus of a portion of the iris; an escape of the crystalline lens into the vitreous humor; in short, a total destruction of the whole organ of sight. It is therefore of the highest importance, as soon as an ulcer appears upon the cornea, to impede its growing larger as much as the nature of it will permit; the painful process should be converted into a healing one, and the surgeon must soon be skillful with more intention, the more sensitively and deeply the ulceration has penetrated. According to Scarpa, the contents of a single ulcer impairs the texture of the cornea so much, that the rest is irreparable. Yet Dr. Vetch asserts, that when a slight covers an ulcer of considerable extent, and is taken off with great caution, so as not to wound the inner parts of the cornea; or when it cannot be removed, if it is slightly washed and dressed, the vision may recover its transparency after two months of time has elapsed.—(*Practical Treatise on Diseases of the Eye*, p. 51.)

That who tampered with the external application can be adopted with benefit for the cure of this disease, before the semi-opthalmia has been reached, or at least diminished; say, it become the opinion, discussed. Experience teaches that local remedies ought, in the very first instance, to be applied to the ulcer; such as are the most efficacious to lessen the increased morbid irritability and stop the destructive process going on; afterwards rest must be taken as well as the opthalmia if it does not subside gradually, as the ulcer heals. It is a fact, confirmed by repeated observation, that it is the state which keeps up the morbidity, not the opthalmia the ulcer. The case, however, is to be excepted in which the liver surface is exposed in the height of a severe opthalmia. Here the first indication is to diminish inflammation before attempting to heal the ulcer.

It is true, that when the little vessels of the retina bleed, the symptoms of acute opthalmia are aggravated; the tendons of the conjunctiva are increased, as well as the purgative state of the vessels; but it is equally certain, that it happens from no other cause than an increased inflammation in the part; in consequence of the increased sensibility in the ulcerated spot of the cornea. As soon as this increase of sensibility is the ulcer of the cornea ceases or changes its violence, the opthalmia ceases with equal speed; and finally, when the ulcer heals, the inflammation disappears gradually, or, at most, requires only the use of an astringent and antiseptic collyria for a few days. Analogous examples every day occur in practice, in ulcers of other parts besides the cornea; particularly in little flat ulcers on the skin of the legs on the apex of the tongue, on the eyelids, on the glans penis, which, as was demonstrated above, at their first appearance assume an uncontained nature, while inflammation of the part is such that they are washed and cauterized very troublesome itching and indeed lead to the part affected. To subside this inflammation we do nothing more, and the vesicular state, that rapid the excessive irritability in these ulcers, and covering the ulcerative process into cicatrization; thus does the increasing inflammation immediately disappear of itself.

Such rapid and good effects may be obtained by cautery. It immediately destroys the vessels exposed out of the border in the ulcerated part, and thus removes the diseased irritability in the part affected; it converts the uncontained surface of the ulcer, and the vesicular discharge upon it, into an indurated and scab, which, as a kind of epidermis, protects the cornea or the neighboring parts upon the ulcer, and it finally changes the process of ulceration into that of granulation and cicatrization.

For converting the ulcer of the cornea, the cautery of which Scarpia gives the preference is the argentea nitrativa. It must be applied to a point, like a crown pencil, and the eyelids being opened perfectly, and the upper eyelid supported by means of Feltz's elevator, the ulcer of the cornea is so to be touched with the spec sufficiently to form an incision. Should any of the cautery descend at the tears, the eye must be copiously washed with warm milk. At the instant the cautery is applied, the patient complains of a most acute pain, but this aggravation is simply compensated by the cure experienced a few minutes after the operation: the patient lies in the eye comes, as it were, to a crust; the eye and eyelids become capable of motion without pain; the flow of tears and the discharge on the wounds of the conjunctiva ceases; the patient can bear a moderate light, and enjoys repose. These advantages last while the incision adheres to the cornea.

On the separation of the scab, sometimes at the end of two, three, or four days after the application of the cautery, the primary symptoms of the disease recur, especially the smarting and burning pain at the ulcerated part of the cornea; the effusion of tears; the return of moving the eye and eyelids; and the aversion to light; but all these inconveniences are soon as diminished before. At their recurrence the cautery, without delay, must remove the symptoms of the ulcerative process, making a good pocket, as it has, upon the whole surface of the ulcer, which, as before, is followed by perfect cure in the eye. The application of this cautery is, if required, to be applied a third time; that is, if, upon the separation of the scab, the extreme irritability in the ulcer is not diminished, and the patient cannot be cured. When the case goes on, sometimes, a great morbid phenomenon in the course

of this disease, that at every separation of the scab, the diseased sensibility of the eye is increased, the liver also becoming its pale red color, assumes a ruddy tinge, first; that, a certain sign that the destructive process which prevailed is turned into a healing one. The morbid state of the vessels of the conjunctiva, and the degree of opthalmia, disappears in proportion as the ulcer draws near to a cure. At this epoch, when the separation of granulations has begun, the surgeon would not very roughly wipe the cornea to remove the use of the argentea nitrativa; it would now produce pain, effusion of tears, and inflammation of the eye; and the ulcer would take on that red, ulcerated aspect, with swollen and irregular edges, which it had at the beginning. Parry has noticed this fact. *Nyctopia* or, at *hæmorrhoides* means, no disorder, flat, no more inflammation, *Scarpia* *hæmorrhoides* *hæmorrhoides* *collyria*.—(Hist. Chirurg. 204.) As soon as the eye is flat in the eye, and granulations begin to rise, whether after the first, second, or third application of the cautery, the surgeon must refrain from the use of every strong caustic, and use only the following collyrium: R. Zinci sulphatis gr. vi. Aq. rose. ℥iij. M. It is to be used every two hours, the eye in the intervals being defended from the air and light by means of opaque glasses and relative bandages. When, besides the ulcer of the cornea, a slight relaxation of the conjunctiva remains, Jaxar's cautery, towards the end of the treatment, introduced between the eye and eyelids, morning and evening, proved successful. It must be adapted to strength and quantity in the particular sensibility of the patient.

To cure those superficial excoriations of the cornea which make an exception in the substance of this membrane, and which, in reality, are only a detachment of the surface, covering the layers of the conjunctiva, first contact with the cautery, the use of caustic is not requisite. The same collyrium, combined with antiseptic, is sufficient. The symptoms which necessarily these slight excoriations or detachments of the cornea are transitory, and when the patient takes care to bathe his eye every two or three hours with the solution of sulphate of zinc, and to avoid too much light and exposure to heat, they soon get well.

According to Dr. Vesali, when the ulcerative process is a body to destroy the membrane which lines the cornea, it can only be checked by measures calculated to subside the inflammation upon which it depends. "As long, therefore, as there is an appearance of activity in the disease, or recurrence of pain, heat, blood-letting by cupping or leeches must be steadily suffered to. The indication of the ulcer being is easily seen in the diminished activity of the inflammation, relief from pain, and the ruddy aspect of the ulcerated part. The application of vegetable, liquid, astringent, balsamic may be used, as such and water only. When called upon in chronic cases, where the incessant perforation of the cornea has been threatened, we test, with great propriety, resort to the operation of penetrating the cornea at a place as remote as possible from the ulcer. Next in importance is a diminution of the action on which the ulcer depends, is the removal by excision of any sloughs formed out from its surface, or detached in the adjoining part of the cornea. Sometimes, but always unnecessary in these indications, we may add some topical applications to the ulcer; a solution of nitrate of silver, the infusion of tobacco or calabar in powder, applied with a soft hair pencil."—(Practical Treatise on Diseases of the Eye, p. 57.) In chronic perforation of the cornea, the membrane of the cornea, this author decidedly condemns the use of the argentea nitrativa in the first manner proposed by Scarpia, observing that, "if the cautery touches by accident the edge of the ulcer, or any part but the apex of the projecting scab, it will soon produce such mischief."

Thus far of ulcers of the cornea, and the best method of curing them is ordinary cautery. However, sometimes, says Scarpia, in consequence of disarrangement, the liver, already very extensive, contains the form of a fungus exuberant upon the cornea, appearing to detain its nourishment from a kind of blood-vessels of the conjunctiva; and on this account it consumes, but independently, a serious remedy is being taken for a bad phlegm. Left to itself, or treated with slight astringents, it produces, in general, a loss of the white eye. It requires the speedy applica-

CUPRI SULPHAS (Sulphate of Copper) is an astringent, and an ingredient in several astringent fluid applications, known for its use, polyptia for the eye, and leucorrhoea for the uterus.

CURETTE (French). An instrument shaped like a female spoon or scoop, provided by the柄, and used in the extraction of the uterus, for taking away any organic matter, which may remain behind the vagina immediately after the lochia has been taken out.

CURVATURE OF THE SPINE. See *Frederick, Disease of*.

DACRYOMA. (From *dacryon*, to weep.) An inflammatory state of one or both the puncta lacrymalia, preventing the tears from passing by their ordinary exit.

DECOCTUM CHAMOMELLÆ. R. Florum chamomellæ, ʒss. Aquæ destillatæ, ℥j. Boil ten minutes, and strain the liquor. A common decoction for febrile affections. (See *Formulations*.)

DECOCTUM PULCARRÆ. R. Infusuræ radicis corneæ rosarum, aquæ destillatæ citæ semion. Decoqui ad octiduum, q̄libet.

The decoction of lichenwood, or woody nightshade, is recommended for some catarrhs of the uterus, proceeding from scrophulous, leucorrhœa, and leucorrhœa. The dose is one or two table spoonfuls, three times a day. An astringent decoction should be added.

DECOCTUM BELLEROPHORI ACID. (Now the Decoction of Turpentine.) R. Pulveris radicis bellerophori, ʒss. Aquæ destillatæ, ℥j. Saturas vases rectificatis, ʒij. Boil the water and powder till only one-half the fluid remains, and when cold add the acid.

This is used as a lotion for curing pueri, porrigo, and some leucorrhœa affections.

DECOCTUM LABELLÆ. (Now Cardiall Flower of Turpentine.) R. Radicis lichenis hyssopifloræ, ʒss. Aquæ destillatæ, ℥ij. This is to be boiled till only four parts remain. The lichenaceous growths resemble an aspidioid, though little plants in appearance. The patient is at first to take half a glass twice, and afterwards four times a day. It operates, however, as a purgative, and the doses must be regulated according as the bowels appear to bear them.

DECOCTUM MARGERITÆ. R. Cerasi medicæ, rosarum, recetis, ʒj. Radicis glycyrrhizæ, coarsius, ʒj. Aquæ destillatæ, ℥ij. Boil the mixture in the water till only two parts remain; and when the boiling is nearly finished, add the lichen root.

The decoction of rosemary has been much prescribed for venereal sores and nocturnal pains in the bones, in doses of three four to eight ounces, three times a day.

DECOCTUM PAPAVERTIS. R. Papaveris mariani capsularum coarsius, ʒss. Aquæ, ℥ij. Boil for a quarter of an hour, and strain. The decoction is used as a sedative fluid.

DECOCTUM QUEBECUR. R. Quercus cortex, ʒj. Aquæ, ℥ij. Boil down to a pint, and strain the fluid.

This decoction forms a very astringent mixture, which is sometimes used for stopping fluxes from the vagina. It also makes a lotion which is of considerable use in curing priapisms, &c. It may be applied to the eye after moderate waste medicine, which it will accumulate there, particularly when a little strain is put upon it.

DECOCTUM SARRAPILLÆ. R. Sarrapillæ radicis coarsius, ʒss. Aquæ destillatæ, ℥ij. The sarrapilla is to be macerated in the first liquor, four days, in a vessel lightly closed. The rose is then to be taken out, bruised, and put into the fluid again. The decoction is to be continued two hours longer, after which the liquor is to be boiled till only two parts remain. Lastly it is to be strained.

DECOCTUM SARRAPILLÆ COMPOSITUM. R. Rosæ, sarrapillæ, hyssopifloræ, ʒss. Mucosæ rosarum coarsius, gutturæ ligulæ, ʒss. glycyrrhizæ radicis recetis, ʒss. Aquæ, ℥ij. Mixture rosarum coarsius, ʒij.

These are to be boiled together the quarter of an hour, and then strained.

Two and the preceding decoction of sarrapilla are much prescribed in cases of venereal sores and pains,

CUPPING. See *Bleeding*.

CYSTOSTOME. (From *cystis*, and *stoma*, to eat.) An instrument made on the same principle as the lithotome, and inserted by the duct of the bladder, for opening the capsule of the crystalline lens.

CYSTOCÆLE. (From *cystis*, the bladder, and *cæle*, a tumor.) A tumor formed by a protrusion of the bladder. (See *Hæmorrhoids*.)

CYSTOTOMIA. (From *cystis*, the bladder, and *tomia*, to cut.) The operation of opening the bladder, for the extraction of a stone or calculus. (See *Lithotomy*.)

D

but while some surgeons hold that it is high time to such cases, others extend it to almost all cases of them. They are also occasionally given in several rheumatic diseases, and to scrophula.

The simple decoction is frequently directed for the restoration of the constitution after a severe disease, sometimes mixed with an equal quantity of port.

The common dose of both the decoctions is from six to eight ounces, three times a day.

The compound eye-pain decoction is the proper medicine of the famous Lisbon diet table, for which it serves a valuable substitute.

DECOCTUM ULMI. R. Ulmi coarsius, ʒss. Aquæ, ℥ij. Boil to two parts, and then strain the liquor.

The decoction of elm bark is often prescribed to women in dysmenorrhœa. Its operation is frequently promoted by giving with it the hydrocyanic solution.

DECOCTUM VERATRÆ. See *Decoction of Veratrum*.

DEPRESSION OF THE SKULL. See *Head*, to *press*.

DEPRESSION OF THE CATARACT. See *Cataract*.

DETERMINATION. When the mind turns itself more rapidly and frequently than is usual, it is said, in the language of surgery, that there is a determination of blood to it.

DIARRHŒA. (From *diarrhoia*, to drip.) A flux of substance; a secretion of continuity. This may be a sort of gastric term, applied to every part of the body, by which the secretory organs are disturbed.

DIGESTION. (From *digestis*, to digest.) By the digestion of a material, or other, one of its parts is broken down to a state in which it is dissolved bodily.

DIGESTIVES. Applications which produce this effect.

DIPHTHOSSIS. (From *diphthosis*, to draw.) One of the ancient divisions of surgery; it signifies the drawing of parts to their proper situation.

DIPLOPIA. (From *diploia*, double, and *opsis*, the eye, or *oculus*, to see.) This diplopia is of two kinds. The ordinary, the patient either sees an object double, triple, &c. only when he is looking at it with both his eyes, and he never is the first time that the object is seen single and right; or else he sees every object double, whether he surveys it with one or both his eyes. The disorder is observed in almost all degrees of weakness. Patients seldom see the two appearances which objects present with equal distinctness; but generally discern one much more plainly and distinctly than the other. The first distinct image which strikes the eye is commonly that of the real object, while the second is indistinct, false, and imaginary. Therefore patients observing under this affection seldom make a mistake, but almost always were when under this and real object. However, there are cases in which the patient sees, with equal distinctness, the two appearances which thus he observes, so that he is incapable of distinguishing the real object from what is false and only imaginary.

The disorder is sometimes transitory and of short duration, and may be brought on in a healthy eye by some accidental cause, generally an irritation affecting the organ. Sometimes the complaint is chronic, sometimes permanent. In particular instances the patient sees objects double, when he has been straining his sight for a considerable time, as, for example, when he has been reading a small print for a long while by the

the style. In this case, the disorder becomes accentuated by starting the eyes for a few moments. There are also instances in which the objects have a double appearance only at a particular distance, and not either when they are nearer or farther off. Sometimes the patient, when objects divide only upon one side; as, for example, when he jumps his eyes to the right-hand, while nothing of the sort is experienced in looking in any other direction. In certain cases, objects appear double, in whatever way the eyes are turned and directed.

The causes of double vision may be divided into four classes. Namely, the object upon which the patient looks at may be represented double upon the retina; which is the effect of the first class of causes. Or, the object may be depicted in one eye differently from what it is in the other, in respect to size, position, distance, clearness, &c. This is the effect of the second class of causes. Or, the object may appear to one eye to be in a different place from that which it seems to the other in respect to the effect of the third class of causes. Or, lastly, the inequality of the eyes serves as a defective, so that the image of an object, though it may appear single to one eye as well as to the other, yet in some unusual situation will seem double to both of them. When the complaint originates from causes of the first and fourth class, the patient sees things double, whether he is looking only one or both eyes; but when it proceeds from the second and third class of causes, the patient sees objects double only when he is looking at them with both eyes, and no longer does he find that these objects put on their natural single appearance.

The following are the chief causes of the first class of a single object being depicted upon the retina as if double. 1. An unevenness of the cornea, which is divided into two or more convex surfaces. There are cases, which show that such an uneven shape may actually be the cause of double vision. (Hallé, *Klinisch. Physiol.* t. 2, p. 85.) According to Beer, this unevenness of the cornea is usually a result of several preceding ulcers of the membrane, in which circumstance, the patient sees with the affected eye not merely double, but three, and even more, of objects before him, as we have examples. (Hallé, *loc. cit.*) However, it must not be supposed that in all the greater number of instances, such unevenness of the cornea, though usually considerable, does not constitute a defect of sight. We have frequently an opportunity of observing cases of this sort after the operation of extracting the cataract. Hence, it would seem that the irregularity must be of very particular shape to produce double vision. The diagnosis of this cause is easy enough, but the removal of it is impracticable; for here it is possible to restore the original shape of the cornea! On this issue, however, Beer delivers a more favorable prognosis than Richter; for he states that when the patient is not deceived, the double vision, from uneven shape of the cornea, will gradually disappear of itself, when proper care is taken of the inflammation, and is particular of the eye. (R. 3, p. 22.) 2. An irregularity of the surface of the crystalline lens, whereby the same is divided into several distinct surfaces, it is supposed, may also be the occasion of diplopia. Such an irregularity may possibly produce the disorder; but it is exceedingly doubtful whether any case of this sort has ever been met with, and, as Richter ingeniously remarks, the investigation is not worth undertaking, as the diagnosis and cure would be equally impracticable. The only possible method of removing the irregularity is by operation of the crystalline lens; yet with the uncertainty respecting the nature of the case, what need would be justified in performing an operation, in which the patient runs wholly unaverted from the danger of losing the sight altogether? A double aperture in the iris, or, as the case is termed, a double pupil, and a division of the pupil from its axis of insertion, have been ascertained as causes of diplopia. (Hallé, *loc. cit.*) See also, *loc. cit.* t. 1, p. 85. 3. However, Richter denies the reality of the first of these causes altogether; he says he has never noticed, where double vision exists, but the effect of these being two apertures in the iris. (Ueber, *How*, *var.* (1822.) But when the disorder actually is produced in this way, the experiment might be made of stopping the two apertures with wax.

The causes of the second class, by the effect of which the object is represented, in respect to its size, position, distance, &c., differently in one eye from what

it is in the other, are for the most part rather possible, than such to have been actually observed. The causes which make objects appear as if appeared contrary to the real case, may sometimes be confined to one eye, so that things are depicted differently from what they are to the other healthy eye, by the patient seeing, as it were, double. Thus, for example, there may be a stronger refraction of the rays of light in one eye than the other; the patient may be a myope with one eye, and a presbyope with the other; and then the object will seem in one eye large, in the other small; to one eye distant, in the other nearly so. The strain of the sight, indeed, is said to have occurred after opening upon a distant object eye. (Huttenlocher.) However, that this is not a constant consequence of opening upon a distant object in one eye, while the other is perfect, is sufficiently clear from what has been said upon this subject in a foregoing part of this work. (See Cataract.) In particular examples, objects which are perceptible as if seen to the patient to have a sloping position. When this is considered that only one eye is thus affected, and that in all things will appear straight, and in the other straight, double vision must be the effect. A few remarks connected with this subject will be mentioned hereafter. (See Sight, Defects of.)

When both eyes are so diseased in an extent, that it becomes situated in the axis of vision of each of these organs, such object is represented in both at the same place, that is, it is depicted upon that part of the retina on which demand sight falls. Thus the object seems to both eyes to be in the same place; and though the two unequal distort the thing, it only represents a single appearance. But when one eye is turned in any object in a different direction from that of the other; that is to say, when one eye is turned as an object in such a way that the object is situated in the axis of vision of this eye, while the opposite eye is so turned that the same object is placed on one side of its axis of vision; in other words, when a person squints, the object is depicted in one eye upon a different part of the retina from what it is in the other; consequently, the object appears to the two opposite organs to be differently situated, and the patient is affected with diplopia. This is the third species of this disorder, which arises from strabismus, as a third kind of unequal causes. Such patients naturally see objects double only when they looked them with both eyes. A lady, whose I frequently see, is much annoyed with diplopia; the effect of depressed vision in the orbit, whereby the eye is forced out of its natural position.

A person who suffers usually has one eye stronger than the other, and the weakness of one of these organs is the common cause of the strabismus. Such a person does not see objects double, located, he only sees with one eye well, and with the other so faintly and imperfectly, that scarcely any impression is made. Hence, every case of strabismus is not necessarily combined with diplopia; indeed, the common kind of squinting is not joined with it. A person affected with strabismus only, does double when the sight of each eye is equally strong, and when the squinting does not depend upon any weakness of one of the eyes, but upon some other occasional causes. The principal causes of the latter sort are of a spasmodic nature, viz. an irritation affects some muscle of the eye in such a manner, that the patient is transported from moving both his eyes according to his will, and from directing them to any object, so that each object may be in a place in the axis of vision of both. On this point, the observations of Sir E. Home are interesting, who has made many accurate collections on the effect of an irregular action of the straight muscles of the eye in producing double vision. (Phil. Trans. 1787.)

Richter states that in the majority of cases, the irritation alluded to is seated in the rectus externus, though he thinks that any other species of irritation may operate upon the eye in a similar manner. This kind of diplopia is frequently attended, on other spasmodic diseases as a symptom. It often accompanies ophthalmia. Sometimes it is the consequence of violent pain. Richter informs us of a man who saw double, and squinted, during a severe headache. He states that he was affected in the same way during a toothache. Sometimes the diplopia is owing to a paralysis of one of the muscles of the eye (Huttenlocher, de Oculorum et Aurium Morborum, quod. 12, art. 26, a pure loss of the conductor muscle?) sometimes to a tension in

few which require two precise positions, or in which the position of the support is more or less stable, therefore of location; by which time he has paid to the student at dislocation, there is great additional difficulty in accomplishing it, and it is often entirely incapable of being effected. If it remains unknown, and consequently uncorrected, the patient becomes a living memorial of the surgeon's ignorance or inattention. Hence this experienced surgeon forcibly admonishes the careful study of anatomy; the want of accurate knowledge of the structure of the joints being the chief cause of the many errors which happen in the diagnosis and treatment of dislocated bones. The following passage cannot be too deeply impressed upon the surgeon's mind: "A considerable amount of anatomical knowledge is required to detect the nature of these accidents, as well as to suggest the best means of reduction; and it is worth to be lamented, that our students neglect to learn themselves sufficiently of the structure of the joints. They often discuss the subject of a limb with great freedom and animation, and then deliver a report, without any examination of the ligaments, the knowledge of which, in a surgical point of view, is of infinitely greater importance; and even learn some of the numerous errors of which they are guilty, when they embark in the practice of their profession; for the injuries of the hip, elbow, and shoulder are scarcely to be detected but by those who possess accurate anatomical information. Even our hospital surgeons, who have neglected anatomy, mistake these conditions; for I have known the pulleys applied to an injured patient in a case of a fracture of the neck of the thigh-bone, which had been mistaken for a dislocation, and the patient cruelly exposed, through the surgeon's ignorance, to a violent and protracted extension. It is therefore proper, that the form of the ends of the bones, their mode of articulation, the ligaments by which they are connected, and the direction in which the larger tendons, should be well understood."—(*Surgical Essays*, part I, p. 3.)

The most important differences of location are: 1. With respect to the direction in which these accidents take place; 2. The extent of the dislocation; 3. The direction in which the bone is displaced; 4. The length of time the displacement has continued; 5. The circumstances which accompany it, and which make the injury simple or compound; 6. And lastly, with respect to the causes of the accident.

1. Every kind of joint is not equally liable to dislocations. Experience proves, indeed, that in the greater part of the vertebral column, location is not admissibly impossible; the pieces of bone being united by extensive articular surfaces, deeply, in their form and direction, and so tied together by many powerful elastic vessels, that very little motion is allowed. Experience proves also, that the strength of the articulations of the pelvic bones can scarcely be affected by morbid efforts, unless these bones be simultaneously fractured. Never has therefore set down a location of joints with continuous surfaces as impossible.—(*Treatise on Medico-Legal Science*, § 4, p. 17.) And Sir A. Cooper observes, and in the end, the union between any two bones is so solid, that dislocations hardly ever occur, except between the femur and osseous vertebra, although the bones are often displaced by fracture.—(*Surgical Essays*, p. 11.)

In the articulations with contiguous surfaces, the facility with which dislocations happen, depends upon the extent and variety of motion in such joints. Thus in the elbow joint of the upper, and particularly at the tarsal, and at the carpal and basal extremities of the metacarpal and metatarsal bones, where flat broad surfaces are held together by ligaments, strong, numerous, and partly interarticular, and where only an obscure degree of motion can take place, dislocations are very difficult, and can only be produced by uncommon violence.

The loose joints, which admit of motion in every direction, are those in which dislocations most frequently occur, such is that of the humerus with the scapula. On the contrary, the glenoid joint, which allows motion only in two directions, two, comparatively speaking, seldom dislocated. The anterior articulation of the larynx is of great extent, and consequently the heads of the bones must be pushed a great way in order to be completely dislocated; and the ligaments are numerous and strong.

2. With respect to the extent of the dislocation, locations are either complete or incomplete. The latter term is applied, when the articular surfaces still remain partially in contact. Incomplete dislocations only occur in ginglymo-articulations, as those of the knee, knee, and elbow. In these, the function is almost always incomplete; and very great violence must have operated, when the bones are completely dislocated. In the elbow, the dislocation is partial, with respect both to the ulna and radius. In the oblique articulations, the humerus are almost invariably complete. However, "like or almost sometimes runs upon the edge of the glenoid cavity, and readily returns into its socket."—(*Cooper's Essays*, part I, p. 14.) The lower jaw is sometimes partially dislocated in a manner different from what is commonly meant by this expression, viz. one of its condyles is jammed, while the other remains in its natural situation.

As Sir A. Cooper has explained, a partial dislocation sometimes occurs at the ankle-joint. "An ankle says he, was dislocated at Guy's, and given to the collection of St. Thomas, which was partially dislocated; the end of the tibia rested still in part upon the astragalus, but a large portion of its surface was united on the os navicularis, and the ilia, altered by this change of place, had formed two new articular surfaces, with their faces turned in opposite directions towards the two bones. The dislocation had not been reduced."

3. In the extremity joints, the head of the bone may be dislocated at any point of their circumference; and the locations are named accordingly upwards, downwards, forwards, and backwards. In the ginglymo-articulations, the bones may be dislocated either laterally, or forwards, or backwards.

4. The length of time a dislocation has existed makes a material difference. In general, recent dislocations may be easily reduced; but when the head of a bone has been out of its place several days, the reduction becomes exceedingly difficult, and in older cases very often impossible. The soft parts and the bone itself have acquired a certain position; the muscles have adapted themselves in length to the altered situation of the bone in which they are attached, and sometimes cannot be lengthened sufficiently for it to be reduced. Indeed, I believe that Sir Astley Cooper's statement is quite correct, that the difficulty in the reduction, arising from the muscles, is proportioned to the length of time that has elapsed since the period of the accident.—(*Treatise on Dislocations*, p. 25.)

Dewees and Boyer believe, that frequently the opening in the capsule ligament soon becomes closed, and hinders the return of the head of the bone into its original situation. However, with regard to the doctrine of the solution being prevented by the capsule ligaments, it is considered by Sir Astley Cooper as groundless or foundation.—(*Surgical Essays*, part I, p. 15, and *Treatise*, &c. p. 25.) Lastly, the head of the bone may become adherent to the parts on which it has been forced.

5. The difference is likewise, in regard to the danger of the case, arising from the extensiveness of a dislocation being attended or unattended with a wound, communicating internally with the joint, and externally with the air. When there is no wound of this kind, the danger is generally trivial, and the dislocation is termed a simple one; when there is such a wound, together with the dislocation, the case is demonstrated compound, and is frequently accompanied with the most imminent peril. Indeed, the latter kind of accident sometimes renders amputation necessary, and in one many instances has a fatal termination.

6. The causes of dislocations are external and internal. A predisposing to such accidents may depend on circumstances internal or external. The great latitude of motion which the joint admits of, the little extent of the articular surfaces; the looseness and division of the ligaments; the looseness of one side of the articular cavity, as of the anterior and inferior part of the acetabulum; and the shallowness of the cavity, as of that of the scapula; are natural predisposing causes of locations.

A partial effect of the removal of a joint, such as a loosening of its ligaments, are also predisposing causes. When the deltoid muscle has been paralytic, the new-weight of the arm has been known to cause such a lengthening of the superior ligament of the shoulder.

ment, and which is adherent to the bone. Thus, in dislocation of the thigh, the bone and ligament turned outwards or inwards, according as the head of the thigh-bone happens to be situated at the inside or outside of the joint. These positions of dislocation in the limbs are of the limbs are permanent, when they depend upon a dislocation; a dislocation admits of several dislocations, and is observable in dislocations, when the same ligament occurs, but can be made to come at once, without any particular effort.

3. The absolute necessity of a limb, or, at least, the facility of performing certain motions, is among the most characteristic symptoms of a dislocation. In some complete fractures of humeral epiphysal joints, the dislocated part is insensibly, or very easily, movable in all motions. Thus, in the dislocation of the osseous humerus, the peculiar disposition of the bone, and the extreme tension of the extensor and flexor muscles, enable the limb in the half-bent state, and at the same time resist every spontaneous motion, and likewise almost every motion which is communicated. In the osseous joints, the partial motion of the osseous which surround the bony bone, being supported by epiphysal membranes; but, in general, symptoms of motion, that by which the dislocation was produced, can be communicated to the limb, though not without evoking pain. Thus, in the dislocation of the humerus upwards, the elbow kindly admits of being put over the side, or of being carried forwards and backwards; but it can be raised up with ease. In the dislocation of the osseous end of the clavicle, the patient can bring the arm towards the trunk, separate it a little from the side, or carry it forwards or backwards; but he cannot raise it in a direct way. Lastly, in complete lateral dislocations of such joints as have alternate motions, the patient has the power of performing motions of the part; but the complete destruction of all the vessels of motion allows the limb to stay every species of continuous motion; and this symptom, which is known never long, makes the nature of the case sufficiently manifest.

Continuing, at Sir A. Cooper has remarked, a considerable degree of osseous resistance for a short time after a dislocation. Thus, in a case, brought into Guy's Hospital, where the humerus had just been dislocated from the osseous end, a great mobility of the arm still remained; but, "in less than three hours, it became firmly fixed in its new situation, by the contraction of the tendons."—(Surgical Essays, part 1, p. 2.)

4. In dislocations attended with elongation of the limb, the general malformation of all the vessels arranged along it, gives to these vessels an appearance as if they lay under the circumference of the bone, and the limb were smaller than its former. The muscles, however, which belong to the side, from which the dislocated bone has become more distant, appear more tense than the others, and form externally a prominent line. This is very manifestly the case with the biceps muscle, when the arm is turned downwards. On the contrary, in dislocations where the limb is shortened, the muscles are relaxed; but, being irritated, they contract and approximate themselves to the shortened state of the limb. Hence the extraordinary swelling of the portion of the tendons to which they belong. We have a striking example of this in the dislocation of the thigh upwards and outwards, where the muscles at the head of the limb form a distinct oblong tumour.

The parts which surround the affected joint also experience alterations in their form, whether occasioned by the dislocated bone, or by the contraction of the muscles. Thus, in dislocations of the thigh, the biceps on the osseous side is enlarged, if the bone is carried upwards; but it is much more relaxed, when the thigh-bone is carried outwards; and its former edge is enlarged higher or lower than in the natural state, according as the limb may have been placed upwards or downwards. In the complete laceration of the osseous back-wards, the thumb is bent, and there is a protruded prominence, owing to the dislocation of the osseous back-wards, in which dislocation it is obliged to participate.

5. The circumstance of the joint itself presents alterations of shape, and osseous articular, and it is to judge rightly of this symptom, correct anatomical knowledge is of high importance.

The form of the joint principally depends upon the

shape of the heads of the bones. Hence, the natural relation of the bones to each other cannot be altered without a change being immediately produced in the external form of the joint. The changes which the muscles passing over the dislocated joint at the same time undergo in their situation and direction, contribute likewise to the alteration of shape, by displaying the harmony of which may be called the osseous of the limb.

When the head of a bone articulated by cartilages, has slipped out of the cavity, instead of the phalanx which previously indicated the natural position of parts, the head of the dislocated bone may be distinguished at some surrounding point of the articulation, while at the articulation itself may be remarked a tumour, caused by one of the neighbouring muscles stretched over the articular cavity, and more deeply may be perceived the outline and depression produced by the cavity itself. The bony relations around the joint, and whose outlines were possibly effaced in the general form of the member, are now made much more apparent by the displacement, and project in a stronger degree than in the natural state. On this part of the subject Sir A. Cooper is particularly correct, when he observes, that the head of the bone can generally be put in its former situation, excepting in cases of translocation of the ligament, and its position is often the best criterion of the accident. The natural prominence of the joint, the joint, either dislocated or become less conspicuous, or the tendons at the ligament, sometimes the osseous cavity, for as dislocation of the shoulder, the osseous cavity is more than usual.—(Surg. Essays, part 1, p. 4.)

The lines made by the contour of the limb and the natural relation of the bones, are so manifestly broken in dislocations of epiphysal joints, that when there is an inflammation swelling the case is more manifest. More certain knowledge, however, and more correct information respecting the kind of dislocation, are to be obtained, by attentively examining the changes of position which the bony prominences forming the articulation of the bones articulated together have undergone, and which are the more obvious in those joints, in which they give attachment to the principal muscles. The natural position of these processes being known, the least error of situation might indicate the well-informed position. Thus, in the elbow-joint, a considerable difference in the respective height, and in the distance between the osseous and internal and external condyles, can be easily distinguished. But the thing is less easy when the surrounding parts are so swollen and come as to make the bony projections deeper from the surface and less obvious to examination. Even then, however, a good surgeon will at least find something to make him suspect the dislocation, and the surgeon will be confirmed when he again examines the part after the swelling has begun to subside. It is of the utmost consequence to make out what the case is as early as possible; for the natural state in which the soft parts are placed forms the swelling along white; and if the surgeon wait till this has entirely subsided before he examines that the bones are injured, he will have waited till it is too late to think of restoring them, and the patient must remain for ever afterwards, crippled at the foot of his limb.—(Nouv. Traité des Maladies Vén. Ch. 2, § 4, c.) It is not only the osseous cavity swelling which may tend to conceal the state of the head of the bone; sometimes a quicker osseous action, from the effusion of blood in the reliable symptoms, and causes an equal difficulty of feeling the exact position of the heads of the bones.—(Nouv. Traité on Dislocation, by Sir A. Cooper, p. 6.)

Dislocations are also sometimes attended with particular symptoms, arising altogether from the pressure caused by the head of the dislocated bone on certain parts. The osseous end of the clavicle has been known to compress the trachea and impede respiration; the head of the humerus may press upon the solitary pieces of nerves, and produce a paralytic affection of the whole arm. In one instance cited by Sir A. Cooper, a dislocated clavicle pressed upon the vagus and endangered life.—(Surg. Essays, part 1, p. 4.)

As Kelland has observed, there are some dislocations which are far more frequent than fractures; of this description are dislocations of the vertebrae, crania, which, indeed, can hardly happen without fracture.

and are almost always fatal; dislocations of the long bones, with protrusion of their ends through the periosteum and skin, and severe inflammation, extensive abscesses, attended with great risk of being followed by large and tedious suppurations, and are subsequently gangrenous.

According to Sir A. Cooper, young persons are rarely subjects of dislocations from violence; but he admits that they do sometimes experience them, and relates an instance which happened in a child seven years of age. In general, their bones break, or their capsules give way, much faster than usually that the articular surfaces are displaced. (*Dict. Nocturne*, part. 8, p. 18; and *Thesaur.*, 4, p. 23.) Supposed luxations of the hip in children commonly turn out to be dislocations of the joint, one instance of which is given by the preceding author, and an example of which I was lately consulted about myself. Also when a dislocation of the elbow is expected in a child, because the bone appears ready to burst into its place, but directly to snap out of it again, the case, according to Sir A. Cooper, is an oblique fracture of the condyle of the humerus. Old persons are also much less liable to dislocations than individuals of middle age; a fact which is accounted for by the attenuation of joints in old subjects being so softened that the violence seems breaks many times them. (*Sir Astley Cooper, Thesaur.*, &c. p. 23.)

RECOVERY.

In general, every unreduced dislocation must deprive the patient more or less completely of the use of the limb; for nature cannot re-establish the natural relations which are lost. There is indeed an effort made to restore some of the motions and the use of the limb to a certain degree; but it is always very imperfectly accomplished, and in the best cases, only a partial degree of motion is recovered. Nature cannot in any way alter the lengthened or shortened state of the limbs; and she can only correct in a very imperfect manner the faulty direction. There are even some cases in which no amelioration whatsoever can be effected; as in complete dislocations of glenohumeral joints.

There are, however, a few exceptions to this general rule. The articular joints are seldom permanently displaced; and so, in the natural case, their motions are very limited, the loss of these motions is consequently of the natural motions not having been restored, is of less importance. Thus, the bones of the osseous, those of the tarsus, and the acetabulum end of the clavicle may be dislocated, and be reduced either imperfectly or not at all, without the function of the limb to which they belong being materially impaired. (*Singer, Traité des Maladies Chir.* 1, 4, p. 54.)

Dislocations of carpal joints are generally much less dangerous than those of glenohumeral ones; for the action of the muscles give a great effort in pushing the bones; the violence done to the collateral parts is less; and the insertion of the soft parts is not so considerable. Even in the same kind of joints, the seriousness of the case depends on the largeness of the articular surfaces, and the number and strength of the muscles and ligaments.

Dislocations of glenohumeral joints, however, are more easily reduced than those of carpal ones, the muscles of which are frequently very powerful, and capable of making great resistance to the efforts of the surgeon. This is frequently seen in luxations of the shoulder and wrist.

It may be said, however, of the luxations of carpal joints, that if they happen the most easily, they are attended with less injury; and that although their reduction may require considerable efforts, yet it can be accomplished, and the motion leaves no ill effects. On the contrary, in dislocations of glenohumeral joints the same pains which produce these cases are frequent, unless there are more serious. The solidity of these joints prevents the treating means from being destroyed except by great violence; and the extent of the articular surfaces does not permit a considerable displacement, especially a complete one, without extensive injury of the ligaments and surrounding soft parts. It is for these reasons, no doubt, that compound luxations and protrusions of the heads of the bones are more commonly seen in the glenohumeral articulations.

The more recent attempts to the cure may it is to

reduce, and, therefore, certain position, the less given to the injury. In this point of view, dislocations of glenohumeral joints are the most serious, because they are more become irreducible.

Simple dislocations are much less dangerous than those which are complicated with contusion, the injury of a large nerve or blood-vessel, inflammatory swelling, fracture, wound, and, especially, a protrusion of one of the articular surfaces. (*Singer, Traité des Maladies Chir.* 1, 4, p. 65, 66.)

Dislocations from violence and suppression in joints, termed spontaneous luxations, cannot admit of reduction: when they arise from the hip-joint, it is not merely in consequence of the ligaments being destroyed, the form of the acetabulum itself is often obliterated. However, there are other spontaneous dislocations from preternatural loosening of the ligaments, where reduction may be accomplished with the greatest facility; though the displacement generally results from the slightest causes.

TREATMENT OF DISLOCATIONS IN GENERAL.

Mr. Pott observes:—By what our forefathers have said on the subject of luxations, and by the descriptions and figures which they have left us of the various methods of what they call their cures and machinements, it is plain, that once upon their object, and what whatever purposes were aimed at or executed by these instruments or machines, were aimed at and executed principally by violence. Many or most of them are much more calculated to pull a man's joints asunder than to set them to rights. Hardly any of them are contrived as to restore the purpose for which they should be used, in a manner most adapted to the nature or position of the parts on which they are to operate. The force or power of some is destructive; it is not always determinable, as to degree, by the operator, and consequently may be too little or too much, according to different circumstances in disease, or more or less nature or thickness in the subject. If, in the degrees of these accidents, an exact knowledge of the symptoms is of the highest importance, a familiar acquaintance with the anatomy is not less essential in the treatment.

In dislocations, as in fractures, says Pott, our great attention ought to be paid to the muscles belonging to the part affected. These are the moving power, and by these the parts, as well as other movable parts, are put into action; while the parts to be moved are in right order and disposition, their motion will be regular and just, and generally determinable by the will of the agent (at least in what are called voluntary motions); but when the said parts are distorted from that order and disposition, the action or power of the muscles from themselves ceases; far from it, they still continue to exert themselves violently, but instead of producing regular motions at the will of the agent, they pull and distort the parts they are attached to, and which, by being displaced, cannot perform the functions for which they were designed.

Hence principally arise the trouble and difficulty which attend the reduction of luxated parts. The more bones composing the articulations, the more surrounding ligaments, would in general admit very little opposition; and the restoring the dislocation would require very little trouble or force, was it not for the resistance of the muscles and tendons stretched to and connected with them; for by examining the fresh joints of the human body, we shall find, that they are only as if moved by muscles and tendons, but also, that although what are called the ligaments of the joints are really connect and hold them together, in such manner as could not well be exceeded without harm, yet in many instances they are, when subject of all commotion, so very weak and lax, and so extensible and distensible, that they do little more than surround the bones and retain the synovia; and that the strength as well as the motion of the parts, depends on great measure on the muscles and tendons connected with and passing over them; and that in those articulations which are designed for the greatest activity, as well as for celerity of motion. Hence it must follow, that as the degree, stability, action, and strength of the principal joints depend so much more on the muscles and tendons in connection with them than on their own ligaments, that the former are the parts which require our first and greatest regard, these being the

parts which will necessarily oppose us in our attempts for reduction, and whose resistance must be either eluded or overcome; third of very different aspect, and which every practitioner ought to be well apprised of.—(See *Pott's Case*, Works, vol. 1.)

That the muscles are the chief causes of resistance is strongly evinced by cases in which the dislocation is accompanied with injury of a vital organ; for then the bone may be reduced by a very slight force. Thus, in a man who had an injury of his pyramis, and a dislocation of his hip, the bone was most easily replaced.—(See *A. Cooper, Surgical Essays*, part 1, p. 38.) In short, any thing which produces spasms or weakness facilitates the reduction, as intoxication, coma, and sickness, paralysis, &c.

The following, which are some of the principles laid down by Mr. Pott, merit attention.

1. Although a joint may have been injured by means of considerable violence, it does by no means follow that the same degree of violence is necessary for its reduction.

2. When a joint has been lacerated, at least one of the bones of which it is composed is detached in that unusual situation by the action of some of the surrounding parts in connection with it; which action, by the immobility of the joint, becomes as it were total, and is not under the direction of the will of the patient.

3. That all the force used in reducing a lacerated joint, be it more or less, be it by hands, levers, ligatures, or machines, ought always to be applied to the other extremity of the said bone, and as much as possible to that only. Mr. Pott argues, that if the extending force were applied to a detached part of the bone, or to the bone before or adjacent, it would necessarily be lost in the articulation which is not lacerated, owing to the yielding nature of the ligaments, and so of falls or as we say in that which is dislocated. This remark, though made by Pott and generally received as true, is very improper; for it tends to state that if you pull at the whole or even, the force does not operate on the hip or shoulder.

4. That in the reduction of such joints as are composed of a global head, moved into a socket, such as those of the shoulder and hip, the whole body should be kept as steady as possible.

5. That in order to make use of an extending force with all possible advantage, and to excite thereby the least pain and inconvenience, it is necessary that all parts serving to the motion of the dislocated joint, or in any degree connected with it, be put into such a state as to give the smallest possible degree of resistance.

6. That in the reduction of such joints as consist of a round head, moving in an acromioid or socket, no attempt ought to be made for moving the said head, until it has by extension been brought forth from the place where it is, and nearly to a level with the said socket. This will show us, says Mr. Pott, a fault in the common rule, and why that kind of rule which Mr. Pott called his comestible, is a much better instrument than any of those, or indeed than it; because it is a lever joined to an extensor; and that capital of being joined with the arm in such position as to rupture the least extensors, and to subvert the joint; besides which it is graduated, and therefore perfectly under the dominion of the operator. It will show us why the old method, by the elbow or ladder, sometimes produced a fracture of the neck of the scapula; as Mr. Pott says it do himself. Why, if a sufficient degree of extension be not made, we are driven over the narrow shoulder, and under the patient's axilla, and thus prove an impediment rather than an assistance by turning the head of the humerus under the neck of the scapula, instead of directing it into its socket. Why the bar, or rolling-pin, under the axilla produces the same effect. Why the common method of bending the arm (that is, the so termed *sementum*), before sufficient extension has been made, prevents the very thing aimed at, by pushing the head in the same under the scapula, whilst the instatement of the extremity for a few seconds only would have carried into its proper place. To the observation that great extension only draws the head of the bone out from the axilla, which it is indeed, but does not replace it in the acromioid scapula. Mr. Pott replies, that when the head of the os humeri is drawn forth from the axilla, and brought

to a level with the cap of the scapula, it must be a very great and very unnecessary addition of external force, that will do us less good than harm. All that the surgeon has to do is to bring it to such level; the muscles attached to the bone will do the rest for him, and that whether he will or not.

7. Another of Pott's principles is, that whatever kind or degree of force may be found necessary for the reduction of a lacerated joint, that such force be employed gradually; that the lower degree be always first tried, and that it be increased gradually.—(See *Pott's Case*, Works, vol. 1.)

The supposition of the reduction being necessary prevented by the capsular ligaments, Dr. A. Cooper considers erroneous. He argues, that in *Dislocationes* from violence, these ligaments are always extensively lacerated; and that the head of the neck of the bone being put or confined by them, is altogether immovable.—(See *Surg. Essays*, part 1, p. 18.) But, in addition to the resistance of the muscles, there are, in all dislocations, three circumstances pointed out by him as causes of the difficulty of reduction. 1. The extensibility of the bone contracts adhesions to the surrounding parts, so that in dislocation, even when the muscles are relaxed, the bone cannot be reduced. In this state, he says the head of a radius, which had been long dislocated upon the external condyle, and which is preserved in the collection of Dr. Thomson's Hospital, is a rigid state to his also seen in a dislocated head of the humerus.—(See *Dislocationes*, p. 25.) 2. The socket is sometimes filled up with ossified matter. 3. A new long socket is sometimes formed, in which the head of the bone is so completely confined that it cannot be extruded without breaking its new indolent.—(See *Surg. Essays*, part 1, p. 23; and *Treatise*, &c. p. 13.)

Dislocations in general cannot be reduced without trouble; but after the reduction is accomplished, it is easily maintained. On the contrary, fractures are, for the most part, easy of reduction; but cannot be kept in this desirable state without difficulty. The greatest extension is resisted, the muscles act, the ends of the broken bone slip out of their proper situation with regard to each other, and the inferior of the limb recedes. As a modern writer has observed, the reduction is only a small part of the treatment of fractures; the most essential point of it is the almost daily care which a fracture demands during the whole time requisite for its consolidation. The contrary is the case in dislocations. Here, as far as the reduction is every thing, if we get out of consideration the less frequent cases in which the dislocation is complicated, and attended with such grave circumstances as render it indispensably necessary to continue for a length of time the almost constant care. But even then the protracted treatment is less for the dislocation itself than for the extraordinary circumstances with which it is accompanied.—(See *Revue, Parallele de la Chirurgie Anglaise avec la Chirurgie Française*, p. 387.)

All the ancient writers recommended the extending force to be applied to the lacerated bone; for instance, above the knee in dislocations of the thigh bone, and above the elbow in those of the humerus. We have stated that Pott advised this plan, and the same practice, which is approved by J. L. Pott, Deverney, and Callison, is almost generally adopted in the present day.

However, many of the best modern surgeons in France, for instance, Falga, D'Apigny, Desault, Boer, Roussin, and Leveillé, advise the extending force not to be applied on the lacerated bone, but on that with which it is articulated, and as far as possible from it. It is said that this plan has two most important advantages: first, the muscles which surround the dislocated bone are not compressed, nor accumulated in spasmodic contractions, which would oppose the reduction; secondly, the extending force is much more considerable than in the other mode; for, by using a long lever, we obtain a greater degree of power.

In Pott's remarks, we find even less information as to the prevailing prejudice against the above practice, and part of the extending force is lost on the joint intervening between the dislocation and the part attached to the extremity made. This notion is quite unfounded, as every man, who efforts for our treatment, must soon perceive. When extension is made at the wrist, the ligaments, muscles, &c. which connect the bones of the forearm with the os brachii, draw the whole of the

extending three centimetres on them, and they must obviously transmit the same degree of extension which they receive in the bone above, in which they are attached. Indeed, this matter seems so plain, that I think it would be an insult to the reader's understanding to say any more about it, than that such resistant sarcomeres have contrary extension can never have taken the trouble to exert for themselves on this particular subject. Whether this force necessary to be exerted in some instances would have a bad effect on the surrounding joint, may yet be a question; but as De-sault's practice was very extensive, and he did not find any objection of this kind, perhaps we have no right to conclude that such would exist.

If, however, the necessary extension to Desault's plan of applying the extending force be attended, the question still remains to be settled, whether this practice is most advantageous on the grounds above specified. This is a point which, perhaps, cannot be at once pronounced decided altogether in the negative or the affirmative, since what may be best in one kind of dislocation may not be so in another. Thus, Sir A. Cooper states, that as far as he has had opportunity of observing, it is generally best to apply the extension in the bone which is dislocated: but first dislocations of the shoulder are exceptions in which he mostly prefers to reduce the head of the bone, by placing his hand in the armpit, and drawing the arm at the wrist in a line with the side of the body, whereby the pectoralis major and latissimus dorsi are kept at a relaxed state. (*Surgical Essays*, part 1, p. 25.)

Extension may either be made by means of assistants, who are to take hold of pulleys or straps, just round the part at which it is judged proper to make the extension; or else a multiplied pulley may be used. In cases of difficulty, Sir A. Cooper thinks the pulley should always be preferred. "When assistants are employed, their exertions are sudden, violent, and sudden if dislocated, and the force is more likely to produce laceration of parts, than to remove the bone to its situation. Their efforts are also often uncoordinated, and their muscles are necessarily fatigued, as those of the patient, whose resistance they are employed to overcome." In dislocations of the hip-joint, and in those of the shoulder which take long irregular pulleys should always be employed.—(*Surgical Essays*, part 1, p. 24.) But whether pulleys be used or not, nothing more need be added to what Mr. Pott has stated, respecting the propriety of using moderate force in the first instance, and increasing the extending power very gradually.

The extension should always be first made in the same direction in which the dislocated bone is moved; but as frequently as the muscles yield, the bone will be gradually brought back to its natural position. Thus the head of the bone becomes disengaged from the parts among which it has been placed, and is brought back to the acetabulum cavity again by being made to follow the same course which it took in coming from it.

Extension will prove quite unreailing, unless the bone, with which the dislocated end is naturally articulated, be kept motionless by counter-extension, or a force at least equal to the other, but made in a contrary direction.

The mode of fixing the scapula and pelvis, in situations of the shoulder and thigh, will be familiarly described.

In dislocations of acromioclavicular joints, extension and counter-extension are only made for the purpose of diminishing the friction of the surfaces of the joints, so that the reduction may be effected more easily.

When the attempt at reduction fails, the want of success is sometimes owing to the dislocation not being perfectly enough, and the great muscular strength of the patient, which commands all efforts to replace the bone.

In the latter case, the patient may be very kind, and not use a superfluous word to make him faint. The opening in the cloth should be made large, because a sudden evacuation of blood is immediately to produce weakness and swooning, than a gradual discharge of it and the oil, for the same reason, may be tied as it stands up. In very difficult cases, the expedient of incision has been recommended, as, when the patient is in this state, his muscles are incapable of making good resistance to extension. These three circumstances, which in this country are almost always met with, are

"The bones to be employed for the reduction of dislocations (says Sir Astley Cooper) are both quadrilateral and triangular. It is generally wrong to insert force only, as it becomes necessary to use it in such a degree as to occasion fracture and injury; which will be shown in the sequel, that the most powerful mechanical means fail, when resisted by immovable muscles. The power of the muscles, in the first instance, is to be duly appreciated; as this forms the principal cause of resistance. The best instrument to use is to be chosen for the purpose of reduction, are those which produce a velocity to escape, and this velocity of it may be best secured by one or other of the following means, viz. by bleeding, warm baths, and caustics. Of these means, I consider bleeding the most powerful; and that the effect may be produced as quickly as possible, the blood should be drawn from a large orifice, and the patient kept in the erect position; for by this method of bleeding, syncope is produced before so large a quantity of blood is made before the patient is lost. However the activity of the muscles must be regulated by the construction of the joint, as the accident happens to all the varieties of construction; it must not be lost down as a general rule, but when the patient is young, delicate, and muscular, the quantity removed should be considerable, and the method of taking it every that which I have described.

Secondly, in those cases where the warm bath may be thought proper, if where it may be considered improper to carry bleeding any further, the bath should be employed at the temperature of 100° or 110° and as the water is the same as in the application of the last remedy, the person should be kept in the bath at the same heat till the relaxing effect is produced, when he should be immediately placed in a chair, wrapped in a blanket, and the mechanical means employed.

Occasionally, I have perceived a third mode of increasing the action of the muscles, by relaxing some of the muscles of the antagonist; but as this is a step, frequently producing vomiting, which is necessary, I rather recommend its application, chiefly to keep up the state of syncope, already produced by the two preceding means, which are relaxing efforts will most readily do, and so potentially overcome the tone of the muscles, that dislocation may be reduced with much less effort, and at a much less distant period from the accident than can be effected in any other way." (*Sir A. Cooper on Dislocations*, vol. 2, p. 24. See also, *Surgical Essays*, part 1, p. 25.) In cases of radical difficulty, the use of anæsthetic laudanum, applied with the warm bath and bleeding, seems rational and judicious; but except in cases of that description, I should prefer the counter-extension, as it overcomes the resistance of the muscles, which will at last overcome the resistance of the most athletic man. Sometimes the resistance made to reduction by muscles, acting in opposition to the will, may be subdued by the patient's attention being suddenly taken from the injured part, at which moment the action of these muscles is suspended, and a very little effort on the part of the surgeon will subdue the bone. A case, illustrating this circumstance, is recorded by Sir A. Cooper. (*Surgical Essays*, part 1, p. 25) and (Pott, loc. cit. p. 24.)

Dislocations of articular joints can seldom be reduced after a month, though by means of great force Desault used to succeed at the end of three or four. Dislocations of acromioclavicular articulations generally become irreducible in twenty or twenty-four days, in consequence of mortification.

The reduction of a dislocation is known by the diminishing of the natural length, shape, and direction, and being able to perform certain motions, not possible while the bone was out of its place. The patient experiences a great and sudden diminution of pain; and very often the head of the bone makes a noise at the moment when it comes into the cavity of the joint.

Sir Astley Cooper believes, that much mischief is produced by attempts to reduce dislocations of long standing by very unskillful persons. He has seen great contractions of the intermuscles, laceration, and laceration of the tendons, and stretching of the peroneal tendon in an anæsthetic and paralysis of the hand, without an abortive attempt to reduce a dislocation in the shoulder. He is of opinion that three months be the shoulder, and eight weeks for the long arm be set down as the period from that moment, when it would be dangerous to make the attempt, unless in progress of very ex-

laced face, or advanced age.—*One* *Fracture of the radius*, *Am. J.*, p. 25.) I have seen two cases, in which very great force was exerted with pulleys, to reduce the thigh-bone at the end of three or four weeks; but the attempts completely failed. However, the success is to be delayed from properly restoring the strength of the muscles previously, by means of moderately doses of arsenic, the weak hand, &c., was not more taken advantage of. A dislocation of the upper head of the radius, of about a fortnight's standing, I have shown twice, at the elbow of two of the most robust carpenters in London.

[The reduction resulting from violence due to the strength of the neighbouring parts in attempts at dislocation, are often much greater than those to which Mr. Cooper alludes in the preceding paragraph. The 5th drawing extract is taken from the last edition of the *First Lecture*, and may be found in a paper by the Philadelphia editor, vol. 2, p. 491.]

On the third volume of the *Repertoire d'Anatomie*, some cases of luxated situation of the hip-joint, in which severe mischief arose from the attempts to reduce the parts, are reported by M. Harbert, M.D. In one case, one of the auxiliary nerves was torn from the spinal marrow; and in others, pneumonia of the lung was the result. After having succeeded completely in several previous attempts, Professor Goussier has within a few years met with two instances in which the auxiliary artery, having formed anastomotic adhesions, was torn, and the death of the patients consequently resulted from the attempts at reduction.

One of these cases is reported in the third number of the *Am. Journal of the Med. Sciences*. The patient, a stout, muscular, athletic man, about six feet high, applied to Professor Goussier on account of a luxation of the left hip-joint at the shoulder-girdle, of some weeks' standing. He was admitted into the Alton House Infirmary on the 6th of March; the anastomotic vessels were pressed until the 15th, when attempts at reduction were made, in the presence of the surgeons and students of the house, which was not accomplished until after the lapse of an hour and three-quarters from the commencement of the operation.

On the 18th, there was a general swelling over the deltoid and pectoral muscles, with a distinct pulsation of an anastomotic character. On the morning of the 19th, it had increased considerably, and in consequence it was decided that the reduction every should be deferred without delay. This was accordingly done by Professor G.

This patient died on the tenth day after the luxation of the shoulder-joint. The details of the case, and the treatment, which was highly interesting, may be found in the 3d No. of the *Am. Journal of the Med. Sciences*. The writer then adds, "These who are acquainted with the professional skill of Professor G. will attribute the failure in this case to the proper cause, the 'fatal adhesion of the artery to the head of the bone,' and a like result must necessarily have followed its reduction by the hands of any other surgeon. As the result of his experience, Professor G. has drawn some conclusions of enormous practical value, and to which we must do much justice cannot be just." "It," says Professor G., "the patient is young, not very muscular, the luxation not accompanied with fracture—if no adhesions have previously been made to secure the reduction, and the head of the bone has not been out of its natural situation beyond five or six weeks, I should advise the attempt to reduce it. But, on the contrary, if the patient is very robust and vigorous, advanced in years, accompanied by labour and to the use of much spirits, and the head of the bone has been long out, I should discourage every attempt at reduction."—*Edin.*

In order to keep the bone from slipping out of its place again, we have only to hinder the first bone moving. When spirits will not sufficiently support the joint, they are very often used, such dislocations of the ankle, wrist, &c. At the same time, the hand, except when at some distance from the body, a restraint of the dislocation will be prevented by confining the arm close to the side in a sling. The proper bandage, applied after such an accident, leaves satisfaction to the patient, than really efficacious. Whatever bandage is used to keep the arm from moving, should be put on the inner side of the arm, as far as possible from

the centre of motion. According to Sir Astley Cooper, the hip is rarely dislocated a second time; but the humerus and the lower jaw very frequently slip again from their sockets, which are shallow. Bandages for the prevention of this return of displacement are, therefore, in such cases, particularly necessary. This is required for some time after the reduction, in order that the repaired ligaments may unite. The strength of the shoulder, Ac. may now be greatly promoted by friction, and pouring cold water over the limb.—(*On Dislocations*, p. 30.)

When a bone is broken and dislocated, an endeavour should be made to reduce the dislocation without loss of time, and then pay attention to the fracture. Also, if there be a compound fracture of the bone, and a dislocation of the shoulder, the fracture is to be secured in splints, and the dislocation then reduced.—(*See A. Cooper on Dislocations*, p. 18.) The case of a bone, dislocated and fractured at the same time, might be attended with considerable difficulty of reduction; for, finally, it is a very uncommon accident.

SYMPTOMS OF DISLOCATIONS.

Common dislocations are those which are attended with a second consequence, with the rupture of the ligamentous parts. Some joints are much more disposed than others to compound dislocations. The shoulder scarcely ever takes place at the hip. Sir Astley Cooper has given one instance of it at the shoulder, and he has seen one of the knee; but the case every frequent in the ankle, elbow, and wrist.—(*On Dislocations*, p. 13.) In most instances, the swelling in the skin is caused by the protrusion of the bone, and sometimes by the part having struck against a hard or an irregular body. Cases of dislocation are frequently attended with great danger, and the same anxiety of judgment is requisite in determining whether amputation ought to be immediately performed, or an effort made to preserve the limb, as in compound fractures, and bad gunshot injuries; and many of the observations which I shall have to offer upon the latter subjects, will, for the most part, be applicable to the present.

When the location of a large joint is compared with an external wound, leading into the capsular ligament, it is a circumstance that has a particular tendency to increase the danger. In many cases, injuries of this description are followed by violent and extensive inflammation, abscesses, mortification, fever, colic, and death. When the patient is advanced in years, much debilitated, or of an unusually sensitive constitution, a compound luxation, especially if attended with much contusion and other injury of the soft parts, and wrongly treated, very often has a fatal termination. This, however, is not the general event of compound dislocations; and whatever may have happened in former times, we now know, that in the present improved state of surgery, these accidents rarely attend cure. This statement may be made, without any reserve being run upon every instance of amputation performed in such cases. I know that this operation is sometimes indispensable directly after the luxation, and I am equally aware, that it may become necessary in a future stage, when violent abscesses or sloughing joined with threatening constitutional symptoms have taken place. My only design is to recommend the caution to cure the general type of compound luxations, but if a case were to present itself, attended with extreme contusion and laceration of the soft parts, I should be as anxious an advocate for amputation as any surgeon.

Mr. Harvesy, surgeon to the Royal Naval Hospital, Plymouth, is speaking of compound dislocations of the ankle, where amputation, "where the lower head of the tibia and fibula are very much shattered; when, together with the compound dislocation of these bones some of the vessels being torn, are displaced and exposed; where any large vessels are divided, and cannot be secured without excessive enlargement of the wound and disturbance of the soft parts; where the constant interference with the neighbouring vessels and muscles, are considerably torn; where the protruded bone cannot by any means be reduced; and where the dislocation is situated at the risk of the membrane, and not likely to endure pain, discharge, and length of confinement."—*A. Cooper's Surgical Essays*, vol. 2, p. 145.) "Pain," as general remarks, these are all

be the cause; but there are exceptions to them. Thus, we find in Sir A. Cooper's publication, several cases in which compound dislocations of the ankle terminated well, notwithstanding the displacement and removal of the astragalus,* other instances of which kind of ancone are to be found in the records of surgery.—(*See Dislocation, in Flexura, Med. Medica*, Percy, in *Journal de Med. Chirurgie*, Nov. 1811, p. 248.) However, if the ends of the tibia and tarseal bones, especially the astragalus and os cuneiforme, are broken, the separation of the bones is recommended as high authority.—(*See A. Cooper's Surg. Essays*, part 5, p. 191.) And with regard to the division of large bloodvessels, Sir A. Cooper states, that he would not at once proceed to amputation on that account. "The case from Mr. Hagelrich of Wittenberg, sent me by Mr. Caden, clearly shows, that the division of the inferior iliac artery does not, if it be well secured, prevent the patient's recovery. I also once saw a compound fracture, almost the middle-joint, accompanied by a division of that artery, and, although the patient was in the hospital, and a barber's servant, who possessed the most constitution to struggle against severe injuries, yet this man recovered without amputation." Now, in Sir A. Cooper's opinion, would all legs be preserved, even if the posterior tibial artery was injured.—(*Vol. vi, p. 180*.) For the method of securing these vessels, see *Articuli*.

The following are the circumstances, when Sir A. Cooper has known give rise to the necessity for amputation of compound dislocations of the ankle. 1. The advanced age of the patient. 2. A very extensive lacerated wound. 3. Difficulty of reducing the ends of the bones. 4. The necessity rather as a reason for saving them off, than for amputation. 5. The extensive shattered state of the bones. 6. Involvement of the tibia towards more greater injury of the bones and soft parts than those towards, and were frequently require amputation. 7. Sometimes the bone cannot be kept reduced, owing to the tibia in the dislocation, onwards being obliquely fractured. 8. Division of a large bloodvessel, attended with extensive wound of the soft parts. 9. Morbidity. 10. Extensive contusion. 11. Extensive suppuration. 12. Necrosis, when the sequestra do not absorb of removal. 13. Very great and permanent debility of the foot. 14. When tetanus comes on, Sir A. Cooper does not approve of the operation. 15. A very intolerable state of excruciating, such as is often met with in very fat subjects, who take no exercise.—(*See Dislocation, &c.*, p. 132, &c.)

The treatment of a compound dislocation requires the reduction to be effected without delay; and with as little violence and disturbance as possible. When the extremity of the bone protrudes, and is surrounded with sand or dirt, as frequently happens from its having reached the ground, it should be washed with warm water, as the best antiseptic matter admitted into the joint will promote and support a suppurative process, and the utmost care should be taken to remove every portion of it adhering to the end of the bone. If the bone be shattered, the finger as it be passed into the joint, and the detached pieces are to be removed, but that is to be done in the most gentle manner possible, so as not to occasion unnecessary irritation; and if the wound be of such a nature as to admit the finger with difficulty, will swallow loose pieces of bone even, be left, the integuments should be divided with a scalpel, to draw off such pieces having removed without violence.—(*See A. Cooper's Dislocation*, p. 129.) If any difficulty of reducing should arise from the bone being girt by the integuments, the operation in them should be divided with a scalpel. The first is then to be joined together, with the temporary pads, cotton-wool bandage, &c. Sir A. Cooper judiciously recommends the portions of the bandage to be sewed together. "I had present under the leg, so that one piece may be removed when it becomes stiff," and by fixing another to its end, before it is withdrawn, the fresh pads may be applied without any disturbance of the limb.—(*Surg. Essays*, part 2, p. 123.) The patient is to be freed from any day, stain of blood, or other extraneous matter, and no lips are to be accurately brought together with strips of adhesive plaster. Sir A. Cooper mentions the finger in the

blood which forms part the best kind of first dressing. The joint is to be covered with linen kept constantly wet with the liquor spiritus acetatis dilutus, or Rosh, what is better, spirit of wine and water; the bandage what is better laid down, and the spirits infused on it is to be loosely laid down, and the spirits infused on it is to be kept perfectly at rest in an upright posture. The patient, if young and young, is to be bled. This last practice may be more easily adopted in the country than in London, or large hospital. All nocturnal the first night or two will be highly proper. Saline draughts, cathartics, and a low regimen, are also indicated during the first few days of the sympathetic fever, which commonly follows, no means an accident.

According to Sir A. Cooper, purgatives should be used with the utmost caution: "So says he, there cannot be a more practice, when a limb has been placed in a good position, and adhesion is proceeding, than to disturb the processes of nature by the frequent changes of position which purges produce; and I am quite sure, that in cases of compound fracture, I have seen patients distressed by their frequent administration. That which is to be done by bleeding and purging the bowels should be effected rather as best in the after the accident, before the adhesive inflammation arises."—(*Surgical Essays*, part 1, p. 311.) Here the practitioner, according to Mr. Earle, would also give opiates to be used without any disturbance of the bowels.

If the case takes a favorable course, the constitutional fever will not be excessive, nor will the joint inflammation of the limb be considerable. Sometimes the wound states more at first without suppuration; a suppuration particularly desirable, as tending to maintain anything close to lessen the danger, by closing the raw, and were, from a compound into a simple one. In other cases the wound is not treated, but the inflammation and suppuration are not violent nor excessive, the constitution is not dangerously attacked, and hopes of ultimate cure may be reasonably entertained. When the wound is changed to land favorably, adhesive plaster, with or without lin, or a jacket of soft soap ointment is the best dressing. In other instances, while the suppuration is copious, and the parts are some and painful, emollient poultices are the most eligible.

When the sympathetic fever and joint inflammation symptoms are over, and much discharge prevails, attended with marks of approaching weakness, the patient is to be allowed more food, and dressed in flannel, calico, porter, wine, &c. If the night is troublesome, he must have opiates; if he remains restless, sedative salt; and, in short, all such medicine as he particular complaints may require are to be prescribed.

When the inflammation of a compound dislocation is violent and excessive, general bleeding, the application of leeches, and the use of fomentations and poultices, are the most likely means of lessening the mischief. Yet it is only in strong habits that venesection is any resort can be prudently pursued in large cities or crowded hospitals.

The following are the instructions delivered by Sir A. Cooper on the subject of dressings. "If the patient complains of considerable pain at the joint, in four or five days the bandage may be used to restrain the motion; and if there be much inflammation, a wet of the joint (or other dressing) should be laid on the wound, or give vent to any matter which may be formed; but this ought to be done with great consideration, as there is danger of increasing the adhesion between, if that be proceeding without opportunity of the local treatment, it will every day and the danger, that the wound will be closed by adhesion, but if in a few days it be not, and suppuration set in, the matter should have an opportunity of coming out, and the last being removed, simple dressing should be applied. After a week or ten days, if there be suppuration with much surrounding inflammation, poultices should be applied upon the wound, before it is in neighborhood, and upon the limb at a distance (the spreading matter should still be employed) but as soon as the inflammation is lessened, the poultice should be discontinued."—(*Surgical Essays*, part 1, p. 123.)

In certain examples, the most suitable treatment is leeching. The joint and limb become affected with considerable pain and swelling, the fever runs high,

* Professor Stevens, of New-York, treated the astragalus in a case of profuse compound dislocation of the ankle-joint, and the case had an early and happy termination.—*News*.

delirium comes on, and the patient may even perish from the violence of the first symptoms, the limb being generally at the same time attacked by gangrene. If these first dangers are avoided, the wound may yet not heal favorably, the inflammation may be considerable, or of an erysipelas nature, large abscesses under the fascia may be formed, the bones may be affected with caries, and the local symptoms and sinking state of the patient may make the only chance of recovery depend upon amputation. But even this operation is sometimes deferred till too late, and the patient must be left to the tender mercies of fate.

Whether given the smallest reflection to the nature of compound dislocations, will perceive that it is often a matter of the highest importance to make a right decision at the very beginning, whether amputation should be immediately done, or an attempt made to save the limb. In some instances, the patient's sole chance depends upon the operation being performed at once, without the least delay, and the opportunity of doing it never returns. The surgeon should take off the limb as soon as he has seen the nature of the injury, and not wait till a general tendency to swelling and gangrene has spread through the tissues, and every action in the system is disturbed. Amputation under these circumstances is undoubtedly done with a very diminished chance of success, and, until certain facts were adduced by Baron Larrey, Mr. Lawrence, Mr. A. C. Hennen, and others, *that* of late years amputation profited—(See *Amputation and Dislocation* first.)

But, besides this first critical period, the surgeon often has to exercise a nice degree of judgment as to the extent of the saw; I mean when the amputation is complete, the wound open, the bones exposed, and the health impaired. Here the practitioner may sometimes err, in taking off a limb that ought to be saved, or he may commit a fatal blunder, and make the patient lose his life, in a fruitless attempt to save the member. No surgeon can form the right practice in this delicate part of surgery; genius alone cannot do it; the opportunity of making observations, and the talent of profiting by them, are here the things which make the consummate surgeon.

It should ever be recollected, it is urged to had compound dislocations, that as young subjects, and in a calid state of the system, many cases will do well, which in old persons, and in the polluted atmosphere of London, and crowded hospitals, would be fatal without amputation.

The regulations of some hospitals are so irritable, that whether an attempt be made to save the limb, or amputation be at once performed, the case has a rapid and fatal termination. According to Mr. A. Cooper, persons who are overloaded with fat "are generally irritable, and bear important accidents very ill; indeed, says he, "they generally do, whatever plan of treatment be pursued."—However, he adds that some corpulent people as soon as a great deal of exercise, form exceptions to the foregoing remark—(*Surgical Essays*, part 2, p. 185).

There is a practice in regard to compound dislocations, which I think ought at all events to be adopted only in a very few cases; I mean the plan of sawing off the head of the dislocated bone. According to Le Boe, this method is recommended by Hippocrates, as a means of amputating and protecting the bone—(*Medicæ Doctrinæ Chirurgicalis*, l. 2, p. 15). However, it seems not to have been sufficient good in ancient times to have obtained a lasting reputation. At last, when a case mentioned by Mr. John Gooch, it first drew into vogue, and it was received as an entirely new proposal. "A compound dislocation says this author, is of a most dangerous nature than compound fractures, the very pain causes it; but if a surgeon acted judiciously in relation to attempt saving a limb under such threatening circumstances, I am inclined to think, from what I have observed, to well be more likely to succeed by sawing off the head of the bone, especially if it has long been out of joint, and exposed to the air."

Mr. Gooch afterwards gives notice of a case in which Mr. Cooper, of Glasgow, saved off the head of the tibia and fibula, and preserved the limb; the patient being able to walk and work for he has been for many years afterwards. Other attempts are also briefly mentioned, in which the lower end of the tibia was sawn off, and the head of the second bone left in situ.

The late Mr. Hey, of Leeds, was known to make Van L—U

trial of this plan in a compound luxation of the ankle. The example, however, which he published, is decidedly reprehensible to the practice, as the following passage will show:—"I was in hopes that this patient would have been able to walk, actually; but in this I was disappointed." He walked indeed without a crutch; but his gait was slow, his leg remaining weak, and his toes remaining numb, which rather surprised me, as his leg was very straight when I caused standing him."

Mr. Hey did not make this case with the view of recommending a similar practice in all cases of this accident; for he had not always adopted it, but was he of opinion, that the same mode of treatment, whether by separating the bones, saving off their extremities, or amputating the limb, ought to be universally practised. When the luxation of the os capitulum and isomphysis is not greater than is sufficient to permit the head of the tibia to pass through them, and when, at the same time the joint or contiguous parts have suffered no other injury, Mr. Hey recommends the re-joining of the bones, and a union of the disjuncts by wires, with the treatment adapted to wounds of the joints—(*Practical Observations on Surgery*, chap. II, art. 5).

That in other cases recorded by Mr. Gooch and Mr. Hey the patients recovered with a new joint, only proves in my mind the great importance and facility of nature, and her successful struggle over the opposition she meets with from bad and unskilful surgery. A limb so injured that it were afterwards to alter than its fellow, and consequently the patient be none or less a cripple. We have seen, that in the only instance published by Mr. Hey, considerable deformity was the consequence of this practice. I cannot help adding my belief, that the position would have experienced more success in the treatment of compound dislocations, had he recommended the objectionable method of sawing to the socket. In such accidents every kind of irritation should be avoided as much as possible, and that the wound may be satisfactorily closed with sewing plastic the observation of an experienced man in St. Bartholomew's Hospital has perfectly convinced me. In this institution, under the disadvantages of the air of London, and an hospital, compound fractures used, at the period when I was an apprentice there, to be treated with marked success; and I feel warranted in ascribing the success to the mode of treatment, which was conducted on the principles explained in the section of the Dictionary.

The most ingenious arguments which have yet been tried in behalf of the practice of sawing off the heads of the bones in compound dislocations of the ankle, are those recently published by Mr. A. Cooper. However, he does not adopt the plan without restrictions. If the dislocation (says he) can be easily reduced, without sawing off the end of the bone; if it be no too extensively broken to remain firmly upon the articular surface being retained; if the end of the bone be not shattered, for then the small loose pieces of bone should be removed, and the surface of the bone be smoothed by the saw; if the patient be not extremely irritable, and the vessels affected with violent spasms, impeding reduction, and causing a displacement at the bones after they have been reduced; Mr. Ashley Cooper advises the incomplete reduction of the parts, and leaving the wound by adhesion. In the opposite circumstances, rather than separate the limb he would cut off the ends of the bones—(*Surgical Essays*, part I, p. 154. Treatise, p. 205).

The only case in which the plan of sawing off the head of the bone can be at all proper, is when a compound dislocation cannot be reduced, notwithstanding the advantages of the wound in the skin, and every other possible means. There is no other mode of preventing the formidable symptoms which would result were the bone left in a state of promiscuity through the integuments; nor is there any better way of alleviating such symptoms after they have actually begun. Mr. Reed gives much proof to the English surgeons for the painless efficacy which they have arrived in cases of this description. Although Fabrice, Bibras, Perard, Desault, Larrey, and several other French surgeons, have, like every English practitioner, endeavored to remove the whole of the integuments, when the bone was totally separated from the synchondrosis, and proceeded in compound situations, yet Mr. Reed acknowledges that the best practice of saving off the

lower end of the hamula, the lower end of the radius, the lower end of the tibia, and also of the fibula, at the same time, originated with, and was first exposed by, English surgeons.—(Perrault, p. 34. Chirurgie anglaise, and in *Chirurgie Française*, p. 205, 1804.)

DISLOCATIONS OF THE LOWER JAW.

The lower jaw can only be limited forwards, and either one or both of its condyles may become displaced in this direction. Every dislocation except that forwards is rendered impossible by the form of the parts. The lower jaw cannot even be dislocated forwards, unless the mouth, just before the occurrence of the accident, be very much open. Whenever the chin is considerably depressed, the condyles slide from behind forwards under the ascending root of the zygomatic process.—The cartilaginous cap which envelops the condyles, and follows them in all their motions, still affords them an articular activity; but the depression of the bone containing the ligaments give way, and condyles glide before the ascending articular surface, and slip under the zygomatic arch. Hence a dislocation mostly happens while the patient is laughing, yawning, &c. A blow on the jaw, when the mouth is wide open, may easily cause the accident. The case has occasionally arisen from the exercise of great force in disengaging the teeth. Dr Astley Cooper has known a complete luxation, that is to say, of both condyles, produced by a boy suddenly putting an apple into his mouth to keep it from the reach of a play-fellow.—(On Dislocations, p. 269.) Whenever the jaw has once been dislocated, the same causes more easily reproduce the accident. In certain individuals the ligaments are so loose, and the muscles so weak, that a dislocation is produced by any slight attempt to yawn, laugh, or (as Lematre has observed) to bite any substance which is rather large.—(Lematre, *Nouvelle Médecine Chirurgicale*, tom. 2, p. 51.) There have been persons who could scarcely ever laugh heartily without their lower jaws being luxated. But of all the causes of this occurrence, yawning alone, even without the violence of any external force, is by far the most common.

When the jaw is depressed, and its angles, to the external sides of which the hamuli are attached, are turned upwards and backwards, if these muscles contract, the greater part of their force tends to bring the condyles into the zygomatic depression.—(Boyer.)

Dislocations of the lower jaw are attended with a great deal of pain, which Boyer ascribes to the pressure produced by the condyles on the depressed temporal alveoli, and those going to the zygomatic process, which serves now, before the mouth of the zygomatic process. The mouth is wide open, and cannot be shut. It is more open to vent the condyles than in those which have continued for some time. An empty space is left before the ear in the natural position of the condyles. The external process lies under the cheek-bone in a prominent, which may be felt through the cheek outside with the mouth. The cheek and temple are flattened by the lengthening of the temporal, zygomatic, and buccinator muscles. The subject feels a large elevation from the mouth, the secretion of which fluid is greatly increased by the irritation of the accident. The arch formed by the teeth of the lower jaw is situated more forward than that formed by the teeth of the upper jaw. During the first five days after the accident, the patient can neither speak nor swallow.—(Boyer.) When only one condyle is dislocated, the mouth is distorted, and turned towards the opposite side, while the fellow-teeth of the jaw do not correspond. However, Mr. Hey asserts, that frequently the position of the chin is not perceptibly altered.—(Practical Observations, p. 229.) The mouth cannot be shut; but it is not so widely open as in the complete luxation.—(Mr. J. Cooper on Dislocations, p. 291.)

When a dislocated jaw has remained unreduced for several days or weeks, the zygomatic arch is well matched. In such instances, the chin becomes gradually approximated to the upper jaw; the patient gradually regains the faculty of speaking, and swallowing; but the zygomatic, and the other muscles from the mouth. The suffering caused by a dislocated jaw, is so great, very often more fatal if the case continues unreduced; and we are not to believe Hippocrates, when he positively declares the accident painful if not reduced before the sixth day. Indeed, Mr Astley

Cooper, in relating the severity of the pain, remarks, that he has seen some very dangerous effects produced on the system, that in some the jaw becomes more closed, and a considerable degree of ankylosis is formed.—(On Dislocations, p. 269.)

Moragni attended a man, two months after such a luxation, which had not been reduced, and found the zygomatic process of the maxilla so fixed, though it was the zygomatic of this sort under his eye.—(Lematre, *Nouvelle Médecine Chirurgicale*, t. 2, p. 58.)

Dislocation of the lower jaw may be reduced in the following manner: The surgeon is first to bring the hand round his thumb, to keep them from being cut by the patient's teeth, and then introduce them into the mouth, as far as possible along the grinding teeth. At the same time he is to place his fingers under the chin and base of the jaw, and while he presses the condyles with his thumbs, he moves the chin with his fingers, by which means the condyles become disengaged from their situation under the zygoma; a gag is then introduced under these parts so rapidly back into the articular cavities again, and then upon a suitable right-angle surface, he has, he is to immediately move them outwardly between the chin and the jaw.

The reduction being accomplished, a firm plaster-cast is to be provided by applying a wire-net bandage, as recommended for the fractured jaw. For a few days the patient should avoid such and so require much resolution.

The zygomatic used to place between the grinding teeth two pieces of stick, and while they rest firm is better to depress the back part of the chin, they must the chin by means of a bandage. The late Dr Ferrius, the dentist, had a patient whose jaw was dislocated on both sides in the direction of a tooth; the reduction was first effected on one side by placing a piece of wood a foot long upon the grinding, and then using the part of it which was laid in the hand. He then put reduced the other condyle in the same manner. Mr Astley Cooper, in reducing a complete luxation of the lower jaw, pressed pulling the patient in the supine position, introducing two cords behind the neck teeth, and then separating the chin.—(On Dislocations, p. 291.) When only one condyle is dislocated, whatever method of reduction be followed, it need only be applied to the side affected.

DISLOCATIONS OF THE VERTEBRÆ.

What have been called dislocations of the spine are considered by the Astley Cooper as really fractures of the vertebra, with displacement of the lower part of the intervertebral substance. The only true dislocation of the spine described by him, are those of the first and second cervical vertebra.—(On Dislocations, &c. p. 37.)

The large surfaces with which the vertebrae support each other, the number and thickness of their ligaments, the strength of their muscles, the high degree of motion which each vertebra naturally has; and the vertical direction of the intervertebral substance, so perfectly opposed to make dislocations of the dorsal and lumbar vertebrae impossible, unless there is some extraordinary violence, and a great deal of pressure. Thus Mr Astley Cooper, in the very extensive experience, has not witnessed a separation of one vertebra from another, through the intervertebral substance, without fracture of the articular process, or, if those processes remained unfractured, without a fracture through the body of the vertebra. On some cases, I shall shortly remark, that they can only result from external violence, that the symptoms would be an irregularity in the disposition of the separate processes, fracture or laceration of the uniaxial and fovea, paravertebral and a morbid state of the lower extremities, the effects of the pressure or other injury, to which the spinal marrow would be exposed. Similar symptoms may ensue when the spinal marrow is directly lacerated by a local contusion, without any fracture or dislocation whatever; and it is certain, that most of the cases mentioned by authors as dislocations of the lumbar and dorsal vertebrae, have only been various kinds of deep and narrow, or fractures of these bones.

The cervical vertebrae, however, not having sufficient anterior surfaces, and having more motion, are occasionally dislocated. The intervertebral of the first and second, and of the first and second

Downward, particularly the hair receptors, is the most common, but fractures of the cervical vertebrae, lower down, though very rare, are possible. Indeed, according to Hoyer, many examples have followed, in which one of the ligamentous bands, or artificial processes of a cervical vertebra have been dislocated, so as to cause a permanent inflexion of the neck, typically the same as that of that of the dislocation. — *Traité des Mal.* (1819, t. 4, p. 114.)

Whether the case published by Mr. C. Ball under the name of a substitution of the spine, ought to be received as an important specimen of a displacement is to be decided from the first dorsal vertebra, I cannot venture to determine. The entire spaces of an ordinary lumbar between these 19th taken; if a considerable space between them; if the interruption of the intervertebral substance; and of an unusual quantity of the spread the distal part of the spine, an circumstance would be the object. "At the back part, the 19th vertebra under the scapula, and on the 19th just was bounded by the scapula," and in the spread spinal a had proceeded through the whole length of the shaft to the caudal region. (C. Ball, Surg. Obs. vol. 1, p. 189.)

Rare specimens, however, that even the larval and adult vermiform may be dislocated.—(*With the following*—p. 71.) Mr. Bell also describes a case of complete dislocation of the tail, dorsal from the first lumbar vertebra, with entire division of the spinal cord. A small portion of bone was broken off.—(*On the anatomy of the Spine and Trachea*, p. 52, pl. 2, fig. 5 and 2.) We learn from Mr. Lawrence, that in the museum of St. Bartholomew's Hospital, there are specimens of lumbar cervical vertebrae. In one of these, the right inferior articular process of the fifth vertebra is dislocated backwards. The portion of the vertebral column above the seat of the injury is twisted to the left, and the body of the fifth, having been partially dislocated, projects beyond that of the sixth vertebra. This displacement would not have been effected without a considerable injury of the dislocation. The upper and anterior part of the body of the sixth and seventh vertebrae have been slightly fractured on the left side. In another case, the inferior articular processes of the fifth cervical vertebra are partially separated from those of the sixth. The bodies of the two bones are partially separated behind. A third specimen exhibits a dislocation of the sixth from the seventh cervical vertebra. The inferior articular processes of the sixth are completely dislocated forward, and its body projects over that of the seventh. Mr. Lawrence has recorded this case, proving that vertebral dislocation both of the inferior processes and body, without fracture, may occur in the cervical region of the spine.—(*See Med. and Surg. Trans. vol. 18, p. 261, 262*.)

RESECTION OF THE HEAD FROM THE FIRST
VERTEBRAE OF CERVICAL.

The os occipital and the cervical vertebrae are usually connected by ligaments, that there is no motion of their being separated. Says an external enemy, and even the accident to happen, it would excessively irritate, by the irreparable compression and injury of the spinal column.

[illegible]

involvement, in those, alternating with pain in the neck, which seems to be about the back of the head, and sometimes elsewhere on morning that part. The head inclines forward, more slender, the face being turned a little down; but, in general, the articulations are affected in one side only, and that side the left in seven out of nine examinations after death. In both sides are affected, the head will incline differently damaged. In some cases things consisting for several weeks or months, and before these symptoms occur, there is often a general improvement, firmer motion, and more mental activities of the head, with the improvement in speaking and remembering matters; the pain becomes more severe and constant; the head finds a little back towards the right and inclines towards the opposite side. The patient complains if the head were too heavy, and beautifully supports it with his hands, when he leaves from the sitting to the lying position, or vice versa. This may be considered a pathognomonic symptom of the affection. Another symptom, which, at this period, shows the true nature of the disease, is a peculiar expression of pain in the occiput, which, combined with the position and stiffness of the head, constitutes so characteristic an inheritance of appearance, that it is enough to leave room if one is eager to recognize it again immediately after the further progress of the case, before in the head, vertebrae, pharynx, cranium and occiput, partial paralysis, particularly of the upper limbs, loss of vision, partial epileptic attacks, and hectic symptoms supervene. Generally, no external change is observable. After in the neck or in the spine, and first observed, it is even easier, consisting of the affected side, which rises and left in the neck. But throughout the pressure in the region of the three upper vertebrae is actually painful, and movement in the affected period of the disease, a feeling of rough surfaces is distinctly perceptible when the head is turned. The patient may restrain the motion in this helpless and painful state, and then dies, either from exhaustion and debility, or, which is more frequent, suddenly and unexpectedly."—*Lancet*, in *Med. Chir. Trans.*, vol. 12, p. 426.) These phenomena of displacement of the atlas may depend upon mere and accidental trauma of the articulation, or upon an erosive of its laminae, or upon a shallow tumor growing from the neighbouring surface of the os occipitale, or of the posterior part of the occipital bone. By dissection, the anterior or posterior arch, or one of the sides of the atlas, has been made to intersect a rib, the left arch and two-thirds of the diameter of the vertebrae broken. Notwithstanding these changes, life may be continued, and the craniæ functions performed satisfactorily, well qualified for enough either for the nervous system a large part, or for the articulations, binding together the head and most of the cervical vertebrae, to acquire gradually. The state of the nervous system, and the movement of the vertebrae of the neck, are necessarily beyond what would be necessary for simply maintaining the spinal marrow, so that the free lateral movements of the head and atlas can be executed without any risk of pressure on that important part. Some spontaneous displacements can occur at first, and in a considerable degree, without impairing the motions of the spinal cord.—(*Lancet*, in *Med. Chir. Trans.*, vol. 22, p. 411.) According to Boyer, the atlas never dislocated and certain when they dislocated, it is surrounded at least with the os occipitale, and only with two or one of the adjacent vertebrae. And other interesting facts, that in cases of this description, the part between the atlas and occiput is never a body one which is displaced and deformed, and, as a disease is very slightly allowed; for the attention of the practitioner, with the atlas, and vertebrae that at the point of the same process with the occiput, are considerably affected. Sometimes the process of the atlas and the occiput retain their natural position with respect to each other, and the atlas alone seems to be displaced between them. Sometimes the neck revolves in out of the place, with respect to the occiput, in the same direction, as the atlas, but not quite so great a degree. Finally, in some other instances, the two vertebrae are related in an opposite direction, so, the occiput, one to the left, the other to the right, or conversely. In case of the cases recorded above, this kind of lateral displacement is especially prominent, and is extensive, that an infirmity, or too loose in the neck, may left between the two

(with those of many other joints)—(On Dislocations, p. 245.)

The clavicle may be dislocated at its sternal extremity, forwards, backwards, and upwards, but never downwards, on account of the structure of the articulation of the first rib. The clavicle forwards is the most frequent; dislocations backwards and upwards are very unusual; and only rarely backwards is still more rare. This last case Dr. Asstley Cooper has never known arise from violence; but he observes that it might happen from a blow on the upper part of the bone, rupturing the capsular ligament and that between the clavicle and rib. The only instance of the dislocation backwards, with which this experienced surgeon is acquainted, proceeded from great debility of the spine. In this extraordinary case, the bone gradually slipped behind the sternum, and protruded so much inconspicuously by an incision in the emphysema, that the late Mr. Barne, of Glasgow, in Stafford, was obliged to remove the sternal extremity. — (Dr. Cooper on Dislocations, p. 244.)

If the dislocation be forwards, a hard, uncompressible tumour is felt, or even seen, on the front and upper part of the sternum. According to Bland, when the shoulder is carried downwards and outwards, the tumour disappears; but in Dr. Asstley Cooper's account, it is said, that the projection of the sternum will subside; if the shoulder be drawn backwards. The clavicle being elevated, the projection descends; if it be drawn forwards, the dislocated extremity of the bone becomes elevated to the neck. The motion of the sternum is painful, and the patient moves the shoulder with difficulty. The point of the injured clavicle (now distant from the central line of the sternum) then exerts. According to the same authority, the dislocation forwards is sometimes complete, only the tip of the capsular ligament being torn. The dislocation forwards is generally produced by a fall upon the point of the shoulder. When the force pushes the clavicle upwards and backwards, but it also frequently happens from falls upon the elbow, when this is separated from the side, and then the clavicle is propelled violently upwards and forwards against the anterior portion of the superior ligament. — (Dr. Cooper on Dislocations, p. 244.)

When the tumour is upwards, the distance between the sternal ends of the clavicle is diminished.

When the dislocation is backwards, there is a depression where the end of the clavicle ought to be, and the point of the bone forms a projection at the first and lower part of the neck, which, as Dr. L. Petit remarks, may compress the trachea, œsophagus, jugular vein, subclavian artery, and nerves. The head is inclined towards the side on which the clavicle itself is situated.

In reducing dislocations at the sternal end of the clavicle, we are to make a lever of the arm, by means of which the shoulder is brought outwards, and when thus brought outwards, it is to be pushed forwards, if the dislocation be in that direction; backwards, if the dislocation be behind; and upwards, if the dislocation be above.

The sternal portion of the arm, and the same apparatus as in fractures of the clavicle, are to be employed. The wedge-like pad, with its thick part towards the axilla, for the purpose of inclining the shoulder backwards, and for the support of the weight of the arm, and a bandage judiciously applied, are especially necessary. In consequence of the obliquity and smoothness of the articular surfaces, the reduction is easy, but great attention is requisite to prevent a return of the displacement.

Dislocation of the acromial end of the clavicle from the scapula. The clavicle upwards is almost the only one that ever occurs. It is possible, however, for the acromion to slip down downwards, and for the end of the clavicle to slip under the acromion. The rarity of dislocations of the acromial end of the clavicle is owing to the strength of the ligaments tying the clavicle and acromion together. While Demme and Boyer, however, represent these cases as being less common than dislocations of the sternal end of the bone, Dr. Asstley Cooper's extensive experience there is no more frequent. — (On Dislocations, p. 245.)

A fall on the top of the shoulder may cause the dislocation upwards. The acromial end of the clavicle then slides upwards on the scapula, and the shoulder is drawn upwards by the muscles which approximate the arm to the body. It has been asserted, that the violent action of the trapezius muscle in pulling the

clavicle upwards, may tend to produce the accident, but, as Dr. Asstley Cooper has remarked, the mechanism of this muscle, without the simultaneous action of great violence, could never draw back the ligaments of the acromial process, which must be broken ere this dislocation can happen. When the projection is low, slight, as Dr. Asstley Cooper has sometimes noticed, the circumstances indicate that the inferior ligament is not ruptured. — (On Dislocations, p. 245.) Falls on the top of the shoulder, a projection of the end of the clavicle under the acromion over the trapezius, and a depression of the shoulder, are symptoms indicating what has happened. The patient also inclines his head to the affected side, and avoids moving his arm or shoulder.

This dislocation is reduced by carrying the shoulder outwards, putting a thick cushion in the axilla, and applying Demme's bandage for fracture of the clavicle (see Fractures) making the turns extend from the clavicle to the axilla, so as to press the lateral end of the bone downwards and keep it in its due situation, at the same time that the elbow is confined close to the side, and supported in a sling, by which means the clavicle will be kept raised and inclined outwards. This plan, which is advised by Boyer, is more efficient than the common practice, which consists in applying a compress to the clavicle of 5 bandages, and supporting the arm in a sling. However, the exact quadrature of the reduction, by any apparatus whatever, is found to be a matter of the greatest difficulty, and some might doubtfully say, impossible; though it is advisable to know that notwithstanding this great obstacle, the use of the last returns very well. In the course of any time, there may several cases in proof of this statement, and one example was shown me by Mr. Bland, St. Vincent, in St. Bartholomew's Hospital. The same observations are applicable to fractures of the sternal end of the bone.

(Dr. James Cooke, of Baltimore, has reported in vol. 4, of the *Ann-Yet Med. and Phil-Journ.* the successful reduction of a dislocation of the clavicle at its superior articulation. — *Revue*.)

PROJECTIONS OF THE CLAVICLE.

Nature, which varies according to the construction of different artists, the nature of their joints, has also been prudent enough to vary the structure of these joints, according to the use of the different portions of their members. To great roundness, some give considerable solidity; for instance, the vertebra column. Others are very strong, but only consist of a slight yielding mass, as we observe in the margin, tibia, &c. Lastly, other joints consist of a great latitude of motion; but their strength is mostly supported by the action of external bodies. Such are in man the shoulder-joint, and that between the sternum and clavicle.

The last kinds of articulation are particularly subject to dislocation, and, of all, not one is so often limited as the shoulder-joint. Highly sensible, that it appears from a comparison, that at some years, this accident at the Hôpital-Neurologique has been so frequent, and even more so than dislocations of all the other bones taken collectively.

Here every thing seems to facilitate the escape of the bone from its natural cavity. An oval shallow cavity, surrounded by a margin of little thickness, receives a semi-spherical head, which is twice as broad as the cavity in the perpendicular direction, and three times as extensive from before backwards. With respect to the ligaments, the joint is only strengthened by a mere capsule, which is thin below, seems yielding against a dislocation; but thicker above, where the acromion, covered process and triangular ligament form an almost insurmountable obstacle to such an accident. With regard to the muscles and tendons of this joint, strong and numerous fasciculi surround the articular surfaces, make them easily move in all directions, well, pushing the head of the os humeri against the different points of the capsule, distal the ligamentous bag; and when their power exceeds the resistance actually formed by it. As for external bodies, when bone is more exposed than the os humeri to the effect of their force?

Thus subjected to the influence of those prodigious forces, the os humeri would be in continual danger of being dislocated, if the scapula, which is as movable as itself, did not furnish a point of support for it, by

displacement, all is resolved. This point of support accommodates itself to the variations in the position of the head of the bone, so that in the movable case of the articular surfaces their strength is in a great measure saving.

The shoulder-joint, which is very liable to luxations or a general strain, is not usually so at all points. There are some, where a dislocation cannot occur; there are others, where, though possible, such an accident has never been observed.

During violent dislocations of the humerus into positions, which are the causes of several tendons, and into positions, which induce the first by the influence of causes previously to be explained. In order to supply the compressions of the various directions in which the head of the humerus is luxated, it is supposed not getting entirely to be located by their limit; one representing its upper edge, another its lower; a third its inner, and a fourth its external one.

The head of the humerus cannot be displaced towards the upper side. Here are situated the acromion and coracoclavicular process, the triangular ligament stretched between them, the tendons of the triceps, supraspinatus, and the fleshy portion of the deltoid, inseparable articulations to the insertion of the head of the bone, prevented by my three apophyses. Besides, what power could dislocate? Supposing there were such a force, the head of the bone must necessarily be driven upwards as well as upwards, so its head would be displaced. This is impossible, because the trunk prevents the lower part of the arm from being dislocated sufficiently upwards to produce this effect.

On the contrary, at the other margin there is difference. At the inferior one, the long portion of the triceps; at the superior one, the tendons of the subscapularis; and at the external edge, those of the infraspinatus and teres minor, will resist any power directed against them, and allow primitive luxations to take place downwards, upwards, or backwards. Downwards, between the heads of the long portion of the triceps and the tendon of the subscapularis, which last, in a case described by Sir A. Cooper, was ruptured (*Ann. Anat.*, part 1, p. 1, and in *Willis's anat.*, 421, 422), upwards between the long subscapularis and tendon of the teres minor, afterwards between the long subscapularis and infraspinatus muscle.

According to Sir Astley Cooper, the os humeri is liable to be thrown from the socket in any of the six positions of four directions: three of these positions are complete; the other is only partial. The first is downwards and forwards, the dislocation runs the acromion, as it is usually called, is upon the head of the bone rests upon the inner side of the inferior cost of the scapula. The second is forwards and the process of acromion, the head of the bone being placed below the middle of the coracoid, and on the external side of the coracoclavicular process. The third is the dislocation backwards, in which the head of the bone can be plainly felt and seen as a protuberance at the back and outer part of the inferior costa of the scapula, upon the dorsum of this bone. The fourth which is only partial, is when the head of the coracoid ligament is torn, and the head of the bone goes against the outer side of the coracoclavicular process. "Of the dislocation in the axilla (says Sir Astley Cooper), I have seen a multitude of instances, of that forwards on the inner side of the coracoclavicular process; although it is much less frequent than that in the axilla: of the dislocation backwards, I have seen only two instances during the practice of my profession for 25 years." (*On Dislocations*, 4th ed. p. 416.)

Sometimes, after the head of the bone has been raised from the articular or pappus part of the capsule, it is carried behind the clavicle, forward a case of "complete dislocation upwards," a species of which was first described by Desault's system. But how the second dislocation only takes place slowly, and when any displacement can hardly be effected, an accident of the axilla allows one constrained by the surface of the bone. Thus is the whorl of the bone, a new variety was formed behind the clavicle, and the humerus adhered by new ligaments to the surrounding parts.

The action of external bodies directed against the arm, but particularly fire, in which this part is fixed against a resisting body, produces a primitive dis-

location, and then the different species of the accident are determined by the particular position of the humerus at the instant when the injury takes place.

Should this bone be directed from the side without being carried either forwards or backwards; should the arm be elevated and the full take place in the side, above the weight of the trunk, almost entirely supported by the bone, forces downwards its upper part, which by this force, forces downwards the upper part of the capsule ligament. Thus a luxation downwards is produced, and this movement may also be facilitated by the continued action of the triceps muscle, particularly upon the triceps muscle, which, as before has just been mentioned, for being at this period invariably strained to support the trunk, they act with the power of a considerable lever; the resistance being the head of the bone, which they draw downwards, with the front part is the lower end of the bone, which is against the ground. Some authors also consider, as the immediate cause of a dislocation downwards, the strong action of the deltoid, which is supposed to strain the head of the bone, and push it downwards through the capsule ligament. In support of this opinion, Billard mentions the well-known case of a woman who dislocated her humerus downwards in lifting up a mirror.

The tendons of the primitive luxation upwards have very little force that of the preceding ones. The elbow is kept separated from the side and internal to the wrist; in falling, the weight of the arm and its humerus, the front part of the capsule is torn, and a luxation takes place in this direction.

The dislocation upwards, as Sir Astley Cooper calls it, backwards is produced in two main parts of way. The elbow is carried forwards towards the upper side; the capsule is stretched upwards, and if a sufficient force act on the head, it is forced out from under the acromion bone. In a full, an arm being pushed against the trunk and kept from, must move sufficiently enough to give such a motion. Hence a luxation upwards, or rather backwards, with the side of the scapula, head, necessarily be necessarily rare, and Desault, in all his expressions, never saw such an accident. Besides, when a full arm is raised from the side and directed forwards in backwards, the weight of the body only operates upon it obliquely, and the head is very little exposed to the action of the triceps muscle, posterior margin, and teres minor muscle. However, a few instances of a dislocation of the head of the humerus in this direction have been recorded. Sir Astley Cooper, in the course of 25 years had met with two examples. In a first subject, Desault remarked a singular inclination of the dislocated arm backwards, its arm was without the presenting on the side an extraordinary elongation and the humerus really slipping under the side of the scapula. (*Précis de Med.*, 4th ed. t. 4, p. 126.)

In the young whose history was published by M. Pons, and in whom a dislocation of the humerus upwards and backwards was seen both by that gentleman and Boyer, there was also the particularity that the humerus was really separated. (*Journal de Med.*, par Cuvier, &c. t. 10, p. 280.) Hence Boyer suspects that this very rare kind of displacement may have been facilitated by some preternatural disposition of the articular surfaces, especially that of the glenoid cavity. No dislocation must occur more frequently than that downwards, in which the influence of the weight of the body, and of the triceps muscle, the acromion, is direct. However, the luxation upwards, or, as Sir Astley Cooper and others call it, backwards, is common.

In all primitive dislocations from violence and not from paralysis of the deltoid, and a gradual yielding of the capsule, I believe the latter part always necessarily loosened. In general authors have paid the little attention to this circumstance, which anatomists have repeatedly demonstrated. Desault had two specimens made of wax; one of a dislocation upwards, the other of one downwards; both of which were cut with in subjects who died at the Hôtel-Dieu. Billard has taken notice of similar facts, and another French surgeon, says, Billard, has observed the same circumstance. I express Billard here should be M. Trucsson, who long ago noticed the location of the humerus, and particularly noticed the attention of surgeons to the subject. (*Ann. Med.*, 6th ed. and 7th ed.)

Desault observes that the capsule may be sufficiently torn to let the head of the bone escape, in

that the opening goes afterward forms a kind of contraction round the neck of the humerus, so as to prevent the return of the head of the bone into the place which it originally occupied. The contraction of this membrane, however, is powerfully denied by Mr. A. Cooper, who remarks, that they who entertain this belief must forget the plastic structure of the capsular ligament, and never witnessed by dissection these extensive lacerations which it suffers in dislocations from violence.—(*Surgical Essays*, part 1, p. 18.)

Several causes may lead to a spontaneous dislocation. If a fresh fall happens while the arm is extended from the trunk, the head of the humerus, which remains confined above, with the utmost facility, the power assuming it in this manner, and is again pushed out of its situation which it accidentally occupies.

A man, going down stairs, meets with a fall, and dislocates the humerus downwards; he immediately sends for Desault, who orders the reduction on the evening. At the next time, the patient, on getting upon a chair, slips and falls again. The pain was never better than when the first accident occurred, and Desault, on being called, instead of finding the head of the humerus as it was in the morning, in the bottom of the axilla, finds it behind the posterior axillary muscle.

The action of motion is a permanent cause of a new dislocation. When the humerus is directed downwards, the posterior margin and the distal end of the upper part of the bone expand and separate, which, only making a weak resistance in their action, changes its position, and takes one in the above axillary direction.

The various motions imparted to the arm just also produce the same effect, according to their direction. Thus, in consequence of painful efforts to reduce the bone, a luxation upwards frequently occurs, or downwards. By the French surgeons, a great deal of our practice has been attached to the division of dislocations of the humerus into primary and consecutive, and perhaps some of their statements of the secondary change in the position of the head of the bone may be exaggerated. That a subsequent alteration in the position of the bone may happen from the causes specified by Desault, are hardly to be questioned. The observations of Petit, Hey, and others, confirm the fact; and I have myself seen a dislocation in the axilla change into one forwards, under the postural regimen. However, Mr. Astley Cooper believes that, excepting from violence and the effect of absorption, the nature and direction of a dislocation are never changed, after the muscles have been contracted.—(*On Dislocations*, p. 416.) Perhaps, with the latter qualification, no great difference prevails between him and other writers.

SYMPTOMS.

In general, the symptoms of dislocations of the humerus are attended with no difficulty.

Whatever may be the mode and situation of the dislocation, there always exists, as Hippocrates has assumed, a marked depression under the axilla, which forms a more evident projection than in the natural state. Almost all the contents of the arca are pulled; some extent is performed in any degree, and they all very loose. The articular surface without the shoulder moving also, because the approximation being no longer able to exercise its function, such it and the shoulder joint, as it were, one body. When the limb is moved, a slight rigidity may sometimes be felt, probably as consequence of the synovia having escaped through the laceration of the capsule.—(*A. Cooper on Dislocations*, p. 415.)

In these symptoms, generally characteristic of every sort of dislocation of the humerus, are to be added such as are peculiar to each particular case. When the luxation is backwards, the arm is a little longer than at the natural state; the natural position of the shoulder is lost in consequence of the oblique line being driven down with the head of the bone; and the patient cannot use the arm. The arm is much or less removed from the axis of the body by the action of the deltoid, the long head of the biceps and supraspinatus muscles being thus directed, and tending to draw the bone posteriorly. The pain which arises from these positions compels the patient to lean towards the dislocated limb, to keep the forearm bent, and the elbow supported on his hip, in such a way that the

arm, having a resting-place, may be sheltered from all painful motion, especially that of the elbow towards the posterior above. Desault often recognized the accident. The head of the humerus may be felt in the axilla; but "only when the elbow is considerably removed from the side."—(*See A. Cooper on Dislocations*, p. 417.) This last circumstance is worthy of particular notice, as the necessity to find the head of the bone limited to mistakes.

With the general symptoms of dislocations of the humerus, a peculiar circumstance is the following: the elbow, separated from the axis of the body, is inclined a little backwards; the humerus seems to be directed forwards in the middle of the clavicle; motion backwards is not very painful, but that forwards is infinitely so; a marked protrusion under the great pectoral muscle; the arm is used by Desault to be a very little longer than in the natural state: by Mr. Astley Cooper it is compared as being somewhat shortened (*On Dislocations*, p. 420), and the profile is the same as in the foregoing case. The corresponding is on the inner side of the humeral bone.

Were a dislocation thus made to prevent itself, it would be peculiarly characterized by a hard tumor under the spine of the scapula; by the direction of the elbow forwards; and by the somewhat increased length of the arm. The motion of the arm would be impaired, but not so great a degree as in the foregoing cases. In the example, related by Mr. Testace, of Hadeney, the arm could be moved considerably either upwards or downwards; but motion forwards or backwards was very limited. And from the observations of Mr. Coles, of Bridgwater, it almost seems that this dislocation may be attended with the peculiarity of the arm being given to the side.—(*A. Cooper on Dislocations*, p. 441—442.)

Many authors, particularly H. Bell, speak of an extraordinary swelling of the whole upper extremity as a frequent consequence of a dislocation humeri. In the time of Hesselius and Richter, these symptoms were not only noticed at the Jussieu, except in very old luxations, and when it was, very beneficial effects were obtained, in certain instances, by applying, for a few days, a moderately tight bandage from the fingers up to the axilla. Richter notices a case in which the arm did not disappear with the cause, but even rather increased; but the dry adhesive bandage had been applied, the swelling was found diminished by touch. Considerable swelling, which sometimes takes place very rapidly, may render the nature of the accident too obscure for a practitioner perfectly unacquainted with all its signs to detect it with certainty; and hence the patient may not have the benefit of right treatment in due time; the bone at length cannot be reduced; a permanently crippled state of the arm is the consequence; the surgeon is used for heavy damages; and his reputation and prospects are ruined.

There is another consequence, to which authors have paid but little attention, though it was known to Aretæus, and was several times observed by Desault. This is a palsy of the upper extremity, arising from the pressure made by the head of the bone, when dislocated upwards, upon the solitary plexus of nerves, and sometimes resulting every means of relief.

Indeed, when the nerves have been long compressed, the affection is very difficult to cure. Desault several times applied the issue above the clavicula. The success which he at first experienced in some patients did not invariably follow in others. But when the head of the humerus has only made, as it were, a momentary pressure on the nerves, and the reduction has been effected soon after the appearance of the symptoms, the paralytic affection often goes off of itself, and its disappearance is powerfully promoted by the use of suitable blisters.

OF THE REDUCTION.

We may refer to two general classes the infinitely various states of malice required for the reduction of a dislocated humerus. The first are designed to push back, by some kind of mechanical force, the head of the bone into the cavity from which it is disengaged, either with or without making previous extension. The others are merely intended to change the head of the bone from the place which it accidentally occupies, leaving it to be put into its natural situation by the action of the muscles.

By the first means we effect every thing; by the second, it limits the interference to the extensile line.

tion of the powers of nature. In the first method, the force externally applied always operates on the bone in the direction of two powers, which resist each other at a more or less acute angle; in the last the power is only in one direction.

All the means intended to operate in the first way, act nearly in the following manner. Something placed under the axilla serves as a fulcrum, on which the arm is moved as a lever, the resistance being produced by the dislocated head of the humerus, which the power is applied either to the lower part of this bone, or the wrist. The muscles of the humerus being pushed downwards and forwards, the ligament of the bone is necessarily moved in the opposite direction, towards the glenoid cavity, into which it slips with ease or less facility.

These operated the machine in celebrated among the ancients and moderns, under the name of the *crucis* of Hippocrates; whether used exactly in the form described by him, or with the numerous variations devised by Paul of Aegina, Astruc, Paré, Deschamps, Frey, &c. It has sometimes a double motion is ascertained to the head of the humerus, as above explained.

The extension usually moves the bone from its natural situation, and is executed in different ways. Sometimes the weight of the body on one side, and the dragging of the end of the dislocation band on the other, tend to produce this effect. Such was the action of the ladder, described in Hippocrates's *Traité des Fractures*, and repeated in modern works. Sometimes the trunk is fixed in an inextensible manner, while the arm is powerfully extended, as is practised in employing the machine of Orsinius, one of the apparatus formerly adapted to the public place where wheelers conducted.

Sometimes no extension is actually executed, and while the end of the humerus is pushed upwards by a body placed under the axilla, the surgeon pushes it upwards into the glenoid cavity.

The following are the elements common to all these contrivances.

However well covered the body placed under the axilla may be to serve as a fulcrum, there is always a more or less considerable chafe, frequently dreadful stretching and laceration of parts in consequence of its application, when the trunk is suspended upon it, as in the instance of the ladder, &c. In this way Paul saw a fracture of the neck of the humerus produced, and even a laceration and amputation of the axillary artery.

Few surgeons have the different kinds of apparatus at hand. Hence trouble and loss of time in getting them; time, which is of so much moment, so the probability is always great that the success is compromised.

When the humerus is coarctated, how can medical means bring back the head of the bone through the track it has taken? For instance, if it is dislocated downwards and towards the axilla, the head of the bone ought to be brought down before it can be replaced. The above means which do not cooperate with the nature, which are the chief and essential agents in the reduction.

Perhaps, however, they might be advantageously employed, when a primitive fracture downwards is quite recent, and when the head of the bone is very near the cavity. Then the inferior end of the scapula presents an inclined plane, along which the end of the bone naturally glides, when propelled by any kind of external force.

Boissier very often employed the following method with great success. While the patient was seated upon a chair of moderate height, he took hold of the hand on the affected side, placed it between his knees, which he moved downwards and backwards, in order to make the extension and draw the head of the bone, while an assistant and back the trunk in order to counter-extension. This was sometimes executed by the weight of the body and effort of the patient. At the same time the surgeon's hands, being applied to the arm in such a way that the first finger of each was put in the hollow of the axilla, and the thumb on the outer part of the arm, pushed upwards, and a little outwards, the head of the humerus, which usually detached with ease into its natural cavity.

Peix describes this plan, but complicated with the use of a cushion, passed under the patient's axilla, and over the surgeon's neck, who contributed to raise the elevated end of the bone, by lifting up his head.

When the fracture downwards was very recent, Boissier successfully reduced it by a still more simple process. Marie-Louise Favre left in going down stairs, dislocated her arm down a wall, and was conveyed immediately after the accident to the Hôtel-Dieu. Boissier having recognised the dislocation, placed his left hand under the axilla, to serve as a fulcrum, while with the right, he pushed the lower end of the arm, to depress the humerus towards the trunk, and at the same time raised the upper part of the bone. The head of the humerus, directed upwards and laterally, immediately returned into its natural cavity, without the least resistance.

Reduction by means of the surgeon's hand is the patient's axilla is a well-known method, which is recommended by Mr Ashley Cooper as the best in three-fourths of recent dislocations. The patient (the observer) should be placed in the recumbent position, upon a table or a sofa, and near the edge. The surgeon then takes a seated position round the arm, immediately above the elbow, upon which he ties a handkerchief. Then, with one foot resting upon the foot, he separates the patient's elbow from his side, and places the foot of the other foot in the axilla. The arm is then slowly drawn with the handkerchief for three or four inches, as the extent which the loose in common cases is easily displaced. If more force be required, a long towel may be tied, with which several persons may pull. Mr Ashley Cooper generally holds the forearm nearly in a right angle with the os humeri, because this position relaxes the ligaments, and lessens the resistance. In many cases, however, he makes the extension at the elbow, a plan in which he finds more force required, but the hindrance is less apt to stop.

Another simple mode of reduction, which Mr Ashley Cooper considers proper for recent dislocations, dislocations, and very old, reduced, unacted persons, is this by means of the surgeon's knee, and fulcrum, is the patient's axilla. The patient is placed on a low stool, on the side of which the surgeon rests his feet, while he takes hold of the os humeri just above the condyles, and applies his knee hard to the os humeri. The arm is then drawn down over the knee, and the head of the bone returns almost easily.—(See Dislocation, p. 421.)

In some cases the preceding methods are inadequate, and greater extension must be made. The following was the practice of Boissier.

The patient seated upon a table covered with a wet towel, a thick linen wrapping is applied to the axilla, on the side affected, and upon this a compress the middle of the free extending bandage is placed, the two ends of which extend obliquely before and behind the elbow, meet each other at the top of the scapular shoulder, and are held there by an assistant, so as to fix the trunk and make the counter-extension. The action of this bandage does not affect the margin of the particular injury and laceration done, in consequence of the pad pressing over them. If this were not attended to, these muscles, being drawn upwards, would pull the humerus in this direction, and thus destroy the effect of the extension, which is to be made in the following manner.

Two assistants take hold of the forearm, above the wrist; or else the towel, distant several inches, if it be applied to this part. The two cranks are to be kept together, and held by one or two assistants, who go to begin pulling in the same direction in which the bone is to be moved. After this first proceeding, which is designed to disengage the head of the bone from its condensed situation, another motion is to be employed, which differs according to the kind of fracture. If the elbow be downwards, the arm is to be gradually brought over the trunk, at the same time that it is gently pushed upwards. Thus the head of the bone being separated from the trunk, and brought near the glenoid cavity, must glide into this situation with great little resistance.

When the fracture is forwards, after the extension has been made in the direction of the humerus, a towel of this kind should be rolled upwards and forwards, in order that the head may be guided backwards, and into its seat, while the traction is continued.

When the head of the bone has been disengaged by the first extension, the motion required to put it in the rest of the extension, should in general be exactly contrary to the course which the head of the bone has taken after getting the glenoid cavity. When there is difficulty experienced in replacing the head of the bone, one should, after making the extension, move the limb about in various positions, according to the different

direction of the dislocation, and the possible joint used. This plan often accomplishes what extension alone cannot; and the head of the bone, brought by such movements towards its cavity, retains also its position during its reduction.

When the dislocation is spontaneous, it is the first extension made in the direction of the displaced bone, which brings back its head to the situation where it was previously lodged, and the case is then to be managed just as if it were a traumatic dislocation.

Thus we see that, except in a few cases, where the beneficial operation of the muscles has been prevented by the violence of the dislocation or by adhesions, and where it was necessary to employ means to force, as it were, the head of the bone into its cavity, to which the muscles could not bring it, almost any employed will spontaneously dislocate till he has put the muscles in a state favorable for accomplishing reduction.

When the muscles are very powerful, or the displacement has continued several days, Sir Astley Cooper, instead of the treatment by the head in the axilla, recommends the patient to be put upon a chair, and the scapula to be fixed by means of a bandage which allows the arm to pass through it, and is buckled on the top of the scapula, so that it cannot slide downwards. A wetted roller is then applied round the arm just above the elbow, and over the roller a strong wooden tape, fixed with what the sailors term the elevated knot. The arm should now be raised to a right angle with the body, and if much difficulty be experienced, even above the horizontal line, it is better to raise more gradually the distal and suprapatellar muscles. Two persons are then to pull the wetted tape, and two the scapula bandage, in opposite directions, with a steady, equal, and continued force. After the extension has been kept up a few minutes, the surgeon is to place his knee in the axilla, with his feet resting upon the patient's chair; he now raises his knee, while he pushes the scapula downwards and forwards, and the head of the bone nearly slips and the glenoid cavity. Sometimes Sir Astley Cooper has seen a protractor motion of the limb made during the extension, just about the reduction.

In old cases, and others attended with great difficulty, from the powerful contraction of the muscles, Sir Astley prefers making the extension with pulleys, because with them, when the resistance is likely to be long, safe and unaltered force is more likely to be avoided than in the preceding method of reduction; and the muscles less apt to be fatigued. The patient sits between two stools, which are secured into the sides of the room; the bandages are then applied precisely in the same way as when the extension is made without pulleys; and the force is applied in the same direction. The surgeon is to pull the cord of the pulley gently and steadily till pain is complained of, when he is to resist the extension already made, but as soon as it. During this time, he should converse with the patient, and direct his mind in other matters. In two or three minutes, more force should be applied, and very gently increased, until pain be again complained of, when another stop should be made. The surgeon should proceed in this way for a quarter of an hour, at intervals slightly raising the limb. When the extension seems great enough, an assistant should hold the cord of the pulley, and keep up the degree of extension, while the surgeon puts his knee into the axilla, and having thrust upon the chair, gently raises and pushes back the head of the bone towards the glenoid cavity, into which it generally returns without the strap needing being when the reduction is effected in other cases. Sir Astley Cooper prescribes the use of the pulleys with extension, the warm bath, and a great deal of continued easy exercise, until relaxation is produced, and why he refers to our general remarks.—(On Dislocations, p. 429.)

When the head of the humerus is dislocated forwards, or under the axilla or the clavicle, Sir Astley Cooper recommends the limbs to be relaxed, and the extension to be made collaterally backwards, and a little backwards. In some instances of this kind, he says, the pain of reduction by means of the head in the axilla will abate, then being taken to apply the force rather more forwards than in a dislocation into the axilla, so that it may press on the head of the bone. However, when the dislocation has continued several days, the resistance greatly increases with pulleys necessary.

As soon as the head of the bone has been drawn below the level of the coracoid process, it is to be pressed backwards with the surgeon's hand or knee, and the elbow at the same moment pulled forwards.—(Op. cit. p. 429.)

The dislocation on the dorsum of the scapula appears, from some cases in Sir Astley Cooper's work, to be reducible by nearly the same mode of extension as has been proposed for the reduction of the dislocation in the axilla. Mr. Coley, of Bridgwater, who has met with two cases of luxation backwards, advises the reduction to be effected by elevating the arm and holding it vertically, so as to roll the head of the humerus towards the axilla, when it is to be kept in this position, while the arm is brought down into a horizontal direction; on the extending force being now relaxed, the bone is easily reduced.—(Op. cit. p. 434.)

In the partial dislocation forwards, or that where the head of the bone lies at the scapular side of the coracoid process, the mode of reduction, according to Sir Astley Cooper, is the same as that employed in the complete dislocation forwards; but it is necessary to draw the shoulders backwards, and as soon as the reduction is accomplished, the bone is to be kept from slipping forwards again by maintaining the shoulders at that position with a bandage.—(Op. cit. p. 435.) The elbow and forearm should also be supported as much forwards as possible in a sling.

In the fracture of St. Thomas's Hospital is a preparation, exhibiting a dislocation of the humerus into the axilla, complicated with a separation of the greater tuberosity by fracture. In Sir Astley Cooper's valuable work on this subject he also recorded a case of compound dislocation of the humerus, which was under the care of Messrs. Blizard and Ingham, of Newcastle, and was cured by amputation.—(P. 435.) Both these accidents must be treated on the same principles as other severe compound dislocations.

For the purpose of preventing the head of the bone from slipping out of its place again, the arm should be kept for some days after the elbow bandaged close to the side, and supported in a sling. Sir Astley Cooper recommends a cushion to be put in the axilla, and a scapular bandage and sling to be applied.—(On Dislocations, p. 435.) After the reduction of a dislocation which has happened downwards, the facility of a fresh displacement is said to depend very much upon the extent to which the tendon of the subscapular muscle has been lacerated.—(A. Cooper's Surgical Essays, part I, p. 7.)

OF SOME CIRCUMSTANCES RESPECTING THE REDUCTION OF THE DISLOCATION OF THE HUMERUS.

1. Necessity of the Opening of the Capsule.

While Desault considers this circumstance as one of the chief impediments to the return of the head of the humerus into the glenoid cavity, Pott and Sir Astley Cooper are of opinion that the capsular ligament can never cross any such difficulty. According to Desault, the surgeon indicated is to enlarge various openings by inserting his fingers. This is fulfilled by moving the limb about freely in every direction, particularly in that in which the dislocation has taken place. Now by pushing the head of the bone against the capsule already torn, the latter becomes lacerated still more, in consequence of being pressed between two hard bodies. The reduction, which is frequently impracticable before this maneuver, often spontaneously follows immediately after it has been adopted. In the Journal de Chirurgie are two cases, by Astruc and Parthous, establishing this doctrine.

Mr. C. White, of Manchester, also believed that the reduction was sometimes prevented by the head of the bone not being able to get through the laceration in the capsule again. He succeeded in reducing some cases which he supposed to be of this nature, in the following manner: having screwed an iron ring into a beam at the top of the patient's room, he fixed one end of the pulleys to it, and inserted the other to the dislocated arm by ligatures attached to the wrist, placing the arm in an erect position. In this way, he drew up the patient till his whole body was suspended; but that too much force might not be sustained by the wrist, Mr. White at the same time directed two other persons to support the arm above the elbow. He now tried to force with his hands to conduct the arm into its place, if the reduction had not already happened, as was some-

dislocation of the humerus—(*Minerva Chirurgica*, Milan, v. 2, p. 446-447.)

DISLOCATION OF THE HUMERUS FROM THE SCAPULA.

Scarcely has the extent of the articular surfaces of the radius and ulna, the strength of the tendons and ligaments surrounding the joint, and the natural position of the bone extension, rendering the articulation a perfect angular synsarcosis, a dislocation of both the radius and ulna from the humerus, is an accident for which a surgeon is sometimes consulted. The radius and ulna are most frequently lacerated backwards; sometimes anteriorly, but very rarely forwards: the latter situation cannot always constitute a fracture of the os humeri. Indeed, it is so uncommon, that neither Pott nor Desault ever saw it with it. The fracture backwards is dictated by the great size of the coracoid process, which, when the humerus is forcibly pushed downwards and forwards, may slip behind it, and ascend as high as the cavity which receives the olecranon in the extended state of the humerus.

Mr. Astley Cooper's experience has taught him to guard with care the different ligaments of the elbow:—1. That of the rotator and ulna backwards. 2. That of both these bones laterally. 3. That of the ulna alone. 4. That of the radius alone forwards. 5. That of the radius backwards.—(*On Dislocations*, p. 485.)

In the fracture backwards, the radius and ulna are several times or less behind the humerus; but the posterior process of the ulna is always extruded above the articular surface, and is forced lodged in the cavity destined to receive the olecranon. The head of the radius is placed behind and above the external condyle of the humerus. The articular ligament, which confines the superior extremity of the radius to the ulna, may be lacerated: in which case, even when the bones are reduced, it is difficult to keep them in their proper places, as the radius tends constantly to quit the ulna.

This accident always takes place from a fall on the hand; for when we are falling, we are led by a mechanical instinct to bring our hands forwards to protect the body. If, in this case, the vapour extremely, instead of resting vertically on the ground, be placed obliquely with the handward in a side of extension, the vapour which is received from the ground will cause the two bones of the forearm to ascend behind the humerus, while the weight of the body pressing on the humerus, directed obliquely downwards, serves as a counterweight to press down before the extended process of the ulna.

The humerus is in a state of half flexion, and every attempt to extend it produces acute pain. The extension of the olecranon, with respect to the condyles of the humerus, is changed. The olecranon, which, in the natural state, is placed on a level with the external condyle, which is itself situated lower than the internal, is even higher than the latter. Posteriorly a considerable protrusion is formed by the ulna and radius. On each side of the olecranon, a swelling appears. A considerable hard swelling is felt on the free part of the joint, arising from the rupture of the lower end of the humerus. The local and general are severe, and the power of bending the joint is in a great measure lost.—(*Mr. Astley Cooper on Dislocations*, p. 486.)

The swelling, which supervenes in twenty-four hours after the accident, renders the ligaments more difficult; but, notwithstanding the assertion of Bayle, I believe the olecranon and internal condyle are never so distended that the distance between them cannot be fully increased. It is true that the rubbing of the constantly present and diverging angles, the humerus may cause a grinding noise, similar to that of a firestone; and some attention is certainly required to establish a dislocation between a fracture of the head of the radius and a dislocation of the humerus backwards. "This dislocation," says Mr. Astley Cooper, "is at first sometimes undetected, in consequence of the great inflammation, which immediately succeeds the injury; but this circumstance does not prevent the reduction, even at the period of several weeks after the accident; nor I have known it thus reduced by bending the limb over the knee, even without great violence being employed."—(*On Dislocations*, p. 478.)

A laceration backwards must be attended with serious injury of the surrounding soft parts. The lateral ligaments are necessarily ruptured, and sometimes the an-

terior ligament of the radius. In a case directed by Mr. Astley Cooper the articular ligament was entire. The biceps muscle was only slightly cut upon the stretch; but the brachialis was extensively so. Probably the lower insertion of the biceps and brachialis internus would likewise be more frequently lacerated by the violent protrusion of the head of the humerus forwards, were it not that only attachments are in some distance from the joint. This accident, however, occasionally takes place, and then the humerus is observed to be freely placed in any position; and not to retain one attitude, as is generally the case in dislocations. The lower end of the humerus, indeed, has been known not only to lacerate these tendons, but to burst the integuments and project itself externally; an instance of which is recorded by Pott, and two years since I saw myself, during my apprenticeship in St. Bartholomew's. Before partly remarking, that it is difficult to operate here, either these circumstances, that brachial artery had broken some short time. In fact, this vessel has sometimes been ruptured, and sometimes of the loss of the contraindication; but this injury of the artery, and the laceration of the tendons and skin, are uncommon.—(*Journal des Med. Chir.* t. 1, p. 515.) Nor if the artery were wounded, would gangrene be necessarily the result; for if my memory is correct, an instance in which the skin was torn, notwithstanding such a complication, is mentioned by Mr. Abernethy in the lecture, though all would the risk would be great.

The following method of reducing the elbow is advised by Boyer:—The patient being seated, an assistant is to take hold of the middle of the humerus, and make counter-extension, while another assistant makes extension active way. The surgeon, seated on the extension, grasps the elbow with his two hands, by applying the forefingers of each to the anterior part of the humerus, and the thumbs to the posterior, with which he presses on the olecranon, in a direction downwards and forwards. This method will possibly be successful if the strength of the patient, or the force continued of the olecranon, render it necessary to employ a greater force, extension is to be made with a truss applied on the wrist, and a truss is to be placed on the upper arm, and the arm must break and as a case of cases of fracture of the humerus.

In Mr. Astley Cooper's method, the patient sits in a chair. The surgeon places his knee on the inner side of the elbow-joint in the bend of the arm, and taking hold of the patient's wrist, bends the arm. As the same time he presses on the radius and ulna with his knee, so as to separate them from the os humeri. Thus the rounded process is pushed out of the posterior fossa of the humerus; and while the pressure is kept up with the knee, the arm is to be flexed gradually, and the reduction is soon effected. According to the same authority, the olecranon may also be reduced by bending the arm over a bedpost, or by bending it while it is clamped in the opening of the back of the elbow-chair in which the patient sits.—(*On Dislocations*, p. 484.)

A bandage may afterward be applied in the form of a figure of 8, encompassing both arm and the arm kept in a sling. The swelling which follows is to be subdued by antiphlogistic means.

At the end of seven or eight days, when the inflammation has subsided, the ambulatory is to be gently moved, and the motion is to be increased every day, in order to prevent an ankylosis, to which there is a great tendency.

In this dislocation, the articular ligament which confines the head of the radius to the extremity of the ulna is sometimes torn, and the radius passes in front of the olecranon. In such cases, penetration and expansion are difficult and painful; though the principal fixation has been reduced, the head may be easily replaced by pressing it from before backwards, and it is to be kept in its place by a compress, applied to the superior and external part of the olecranon. The compresses are to be taken off every two or three days, and the joint gently bent and extended, in order to prevent ankylosis.

In a modern publication, an instance of a dislocation of the head of the radius and ulna backwards is related, where the lower end of the humerus protruded through the olecranon, and as it could not be reduced, it was amputated. The patient, a boy, recovered the full use of his arm.—(*Journal, Pract. Chir.* de l'Europe, Compagnie Parisienne, 34, p. 101.)

A luxation forwards should be treated as a fracture of the os humeri, with which it would be inevitably accompanied. Here, as occasion of the great injury done to the soft parts, it would also be right to bleed the patient copiously, and put him on the antiphlogistic regimen.

With respect to lateral luxations, either upwards or downwards, they are always incomplete and easily corrected. In the case upwards, the os humeri remains situated on the back part of the external condyle. The position of the ulna backwards is even greater than if the dislocation of both bones directly backwards, and the radius forms a pyramidal point and is on the outer side of the os humeri. By moving the hand, the rotation of the head of the humerus can be distinctly felt. In the lateral dislocation backwards, the ulna may be driven upon the internal condyle, so as to produce an irregular hollow above it, and the rotation of the head of the os humeri can be distinctly felt. Sometimes when the ulna is driven upon the internal condyle, it still projects backwards, as in the external lateral dislocation, in which circumstance the head of the radius is in the posterior fossa of the humerus, and the entire condyle forms a considerable projection—(A. Cooper, op. cit. p. 471.). Boyer advises the reduction of lateral dislocations to be effected by extending the humerus and forearm, and at the same time pushing the extremity of the humerus and the heads of the ulna and radius in opposite directions.

According to Mr. Astley Cooper, in each of the lateral dislocations, the reduction may be performed by bending the arm over the knee; and in recent cases, as one which he relates, proves, by supposing that the humerus may be more readily disengaged by flexing the arm; he when this is done, the humerus and radius drive the heads of the ulna and radius into their right places again.—(P. 472.)

These luxations cannot be produced without considerable violence; but when the bones are restored, they are easily kept in their place. It will be sufficient to pass a roller round the part, to put the forearm in a middle state, neither much bent nor extended, and to support it in a sling. But useful information is to be rejected from the injury done to the soft parts. Is it to prevent, or at least mitigate it, the patient is to be kept two or three times and put to a low diet, and the articulation is to be covered with the lotus plantain oint, or an emollient poultice. It is scarcely necessary to repeat, that the arm is to be putted as soon as the state of the soft parts will admit of it.—(Boyer, *op. cit.* p. 471.)

A dislocation of the humerus backwards is said to occur less times as frequently as lateral luxations; and those forwards are so rare, that no extension whatever can be drawn.—(Macleod's Clin. & Surg., A. 1.)

All recent instances of the elbow are easily reduced and as easily maintained; for a displacement is prevented by the reciprocal manner in which the articular surfaces receive each other, and by the mutual expansion and contraction. This consideration, however, should not lead us to omit the application of a bandage in the form of a figure 8, and supporting the arm in a sling.

DISLOCATIONS OF THE RADIUS FROM THE ULNA.

The majority of writers on dislocations of the forearm have not separately considered those of the radius. The subject was first well treated of by Desault. However, dislocations of its lower end remained unnoticed until Desault, reviewed the profession with a particular regard to them.

The radius, the movable agent of pronation and supination, with regard to the ulna, which serves its immovable support, by means of two articulations; one above, slightly convex, broad internally, rough externally, and corresponding to the little sigmoid cavity of the ulna, in which it is lodged; the other below, concave, semicircular, and adapted to receive the convex edge of the ulna. Above, there are two points, differing in their motion, articular surfaces, and ligaments.

Above, the radius is pivoted and supported only round its own axis; below, it turns about the axis of the ulna. Here, being more extensive and powerful, than they are above. The head of the radius, turning on between axes in the annular or veterinary ligament,

cannot dislaid in any direction. On the contrary below, the radius, in performing motions, strikes the posterior part of the capsule, and presses it against the immovable head of the ulna, which is apt to be pushed through, if the motion be forced. A similar event, in a contrary direction, takes place in supination. The front part of the capsule being rendered tense, may now be dislaid.

Add to this disposition the difference of strength between the ligaments of the two joints. Below and yielding below; thick and firm above, their difference is very great. The upper head of the radius, supported on the annular immovable articular surface of the ulna, is protected from dislocation as much as its position. On the contrary, as lower end, carrying along with it in its motions the form of the capsule, which it supports, cannot itself derive any solid stability from itself.

From what has been said, the following conclusions may be drawn: 1. That with more causes of motion, the lower articulation of the radius has less means of resistance; and that under the triple consideration of muscles, ligaments lying the articular surfaces together, and the form of these surfaces in each other, this joint must be very subject to dislocation. 2. That, for opposite reasons, the upper joint is very secure, so that, though, be rarely exposed to such an accident. The latter requires more consideration, since it is when the annular ligament of the radius is torn in a fracture of both heads of the radius and also backwards, and particularly causes the returning to a dislocation of the upper head of the radius from the lower sigmoid cavity of the ulna, as a single and unresisted injury, suddenly produced by an external cause, and, therefore, either to be combated with the same above specified, or with other examples in which the displacement happens slowly, especially in children, is consequent on a disease at various states of the ligaments.

However, some instances of dislocation of the upper head of the radius, suddenly produced by external causes, are recorded by Desault; the particulars of another case were communicated to the French Academy of Surgery; and I have been informed of two examples which were met with in this country.

Two of these cases occurred in the practice of Mr. Duane, of Scarborough; one in that of Mr. Lawrence; and the other was attended by Mr. Ellis. Mr. Astley Cooper has himself seen six examples of the dislocation of the head of the radius forwards. Baron Boyer says, that many instances are now known in which the upper head of the radius was dislocated backwards; indeed, in opposition to what Desault insisted, he asserts, that dislocations of the lower joint, between the radius and ulna are more rare than those of the upper joint between the same bones. The latter assertion he has twice seen himself.—(Med. Clin. L. 4, p. 245.)

The dislocation backwards is described by the author, as occurring more readily and frequently in children than in adults or old subjects. The reason of this circumstance is ascribed to the less firmness both of the ligaments and of the condyles three of the extreme articular, which three, in a more advanced age, contribute greatly to strengthen the external ligament. In a child, too, the little sigmoid cavity of the ulna is smaller, and the annular ligament, extending farther round the head of the radius, is longer, and more apt to give way. Hence, is a subject of this description, efforts, which may not at first produce a dislocation, if frequently repeated, cause a gradual elongation of the ligaments, a change in the internal position of the bones, and at length, a degree of displacement as great as in a case of dislocation (marked) and immediately effected.—(Treat. des Mal. Clin. L. 4, p. 245.)

Another fact mentioned by Boyer is, that the inferior surface of the upper head of the radius backwards is always complete, articular surfaces being perfectly separated both from the lower end of the humerus, and from the little sigmoid cavity of the ulna. The usual cause of the accident is a pressure of the forearm, carried with great violence beyond the natural limits.

In a dislocation of the head of the radius backwards, the forearm is bent, and the hand fixed in the state of pronation. Dislocation can neither be performed by the action of the muscles, nor by strength. Here; and

every attempt to separate this movement produces a considerable increase of pain. The head and fingers are moderately bent, and the upper end of the radius may be observed forming a considerable projection behind the lower end of the humerus. In the case which was mentioned to me by my friend Mr. Lawrence, the head of the radius lay upon the outside of the external condyle.

Sir Astley Cooper has given some a dislocation of the upper end of the radius backwards, in the living subject; but a case was brought for dissection this day from St. Thomas's Hospital, which had such a dislocation which had never been reduced. The head of the radius was thrust behind the external condyle, and rather to the outer side of the lower extremity of the humerus. The lower part of the coronary ligament was seen through, as well as the oblique one, and the caputulum was generally luxated.

In the first of case described by Sir Astley Cooper, where it seems the limb was dislocated, this appeared to surprise everyone, that the bone would be easily reduced by bending the arm.

The reduction is to be accomplished by extending the forearm, and endeavouring to bring it into the scapular position at the same time that the supinator acts to press with his thumb the head of the radius forwards towards the lower tubercle of the humerus, and into the little sigmoid cavity of the ulna again. Success is indicated by the patient being now able to perform the supinator motion of the hand, and to bend and extend the elbow with freedom.

For the purpose of preventing a return of the dislocation, and giving others an opportunity of repeating the little experiment, measures must be taken to hinder the protrusion of the head. Boys sometimes do with this view a roller, compresses, and a sling; but it appears to me, that a slight, extending band to the extremity of the fingers, and laid along the spine of the scapula with a pad of sufficient thickness to keep the hand daily elevated, would be right, in addition to the sling, roller, &c.

In the dislocation of the head of the radius forwards, this part is thrust into the hollow above the external condyle, and upon the coronoid process of the ulna. According to Sir Astley Cooper, the forearm is slightly bent, but cannot be bent to a right angle, nor completely extended. When it is moderately bent, the head of the radius strikes against the fore part of the os humeri. The hand is in the prime position, and if raised, the corresponding motion of the head of the radius can be felt at the upper and front part of the elbow-joint. The os coracii or acromion, the oblique ligament, the front of the caputulum, and a portion of the intracapsular ligament, are torn.

Sir Astley says, that the cause of this accident is a fall upon the hand when the arm is extended; at which event, the radius receives the weight of the body, and is forced up by the side of the ulna, and thrown over the external condyle upon the coronoid process. In two of the cases recorded by him, the reduction could not be accomplished; in the third it was effected during a struggle by extending the forearm, while the surgeon rested on the patient's foot. In the fourth, the hand was placed on a wall, and his arm bent over the back of it, in which state continued till he made him bend, without extending the ulna. The left hand of the os humeri, and the reduction was accomplished in a few minutes. The chief things to be observed are, so in the treatment act upon the radius alone, without the ulna, and during the extension to get the hand to extend. (*Practical Surgery*, p. 474-477.) In the latter position the forearm should also be kept by means of a splint, pad, and bandage, until the first pain is healed.

DISLOCATION OF THE LOWER END OF THE RADIUS.

The radius may, I believe, act of the passive and passive motions. Thus, Denham has published the case of a labourer, who dislocated the lower end of the radius forwards, by a powerful pressure of her hand in twisting a wet cloth. (*Hopk. Trans. de Med. Chir.* 1, 4, p. 214.)

2. External force, moving the radius violently into a sudden position, and rupturing the ligament, and breaking the joint.

There are two kinds of dislocation: one of

the radius forwards; the other backwards. The first is very frequent, the second is much less so. The latter case is now mentioned by Sir Astley Cooper, and never presented itself to Denham but once in the dead body of a man, both of whose arms were dislocated, and of whom the particulars could be learned. The head of the ulna was pushed in front of the sigmoid cavity of the radius, and in contact with the os capitulum, in which it was covered by a singular ligament. (*Hopk. Trans. de Med. Chir.* 1, 4, p. 202.) The latter writer has also recorded one instance of this rare accident. (*Phil. ed.* p. 223.)

In the dislocation of the lower end of the radius forwards, described by Sir Astley Cooper, this part is thrust over the front of the caputulum, and lies upon the os acromion and the os coracii.

The positions of the lower end of the radius, described by Denham, are the same as those named by Sir Astley Cooper dislocations of the lower end of the bone from the radius, and differ from the case called by him a fracture of the radius only at the wrist, inasmuch as the hand is not thrown in the opposite direction to that of the radius; but this bone is merely displaced from the os coracii, another surface of the ulna, its limit going along with it. This displacement makes a singular difference in the mode of reduction, with reference to the direction in which the hand is to be pushed. In the location of the lower end of the radius forwards, described by Denham, the apparatus are constant position of the forearm; an inability to perform supination, and great pain on the thing attempted; an unusual position at the back of the fist, in consequence of the protrusion of the little end of the ulna through the sigmoid; the position of the radius is very forward than natural; resistant adhesion of the thumb, which is almost always exposed; a nail long, some of the fingers, and very often of the fingers, which posture cannot be changed without considerable pain. The outer side of the hand is twisted backwards, and the hand forwards. The protrusion rests on the fore part of the wrist by the head of the radius is very evident, and, in Sir Astley Cooper's case, the styloid process of the radius is no longer strained opposite to the os trapezium. This case, he says, usually happens from a fall while the hand is bent back. (*On Dislocations*, p. 503.)

Sometimes the lower end of the radius is driven through the skin at the hands of the wrist, between the radial artery, and the veins formed of the dorsal veins of the wrist and fingers. Cases of this description, when well managed, generally have a favorable termination, as we see in the case reported by M. Thompson. (*Ann. de Med.* p. 204.)

If the situation of the opening in the skin expose its impediment to reduction, the integuments should be divided with a knife.

A fracture of the radius backwards is characterized by symptoms the reverse of those above mentioned. They are, a violent expansion of the limb; inability to put it upon; pain on making the attempt; a tumor in front of the forearm formed by the head of the ulna; a projection backwards of the large head of the radius; and adhesion of the thumb.

When the dislocation is forwards, an assistant is to take hold of the elbow, and raise the arm little from the body; while another is to support the hand and fingers.

The surgeon is to take hold of the end of the forearm, with both his hands; one applied to the inside, the other to the outside, in such a manner that the two thumbs meet each other in front of the limb, between the ulna and radius, while the fingers are applied to the back of the wrist. He is then to endeavour to separate the two bones from each other, pushing the radius backwards and upwards, while the ulna is bent to its proper place. At the same time, the assistant, holding the hand should try to bring it into a state of supination, and consequently the radius, which is its support. Thus pushed, in the direction contrary to that of the dislocation, by two powers, the radius is moved backwards, and the ulna comes into the vicinity of the caputulum, and into the sigmoid cavity.

Sir A. Cooper, who describes how once under the name of a dislocation of the lower end of the radius backwards reduces it by pressing the bone forwards, and maintains the reduction with splints well padded, and a compress of leather over the end of the joint. (*On Dislocations*, p. 492.)

It should present a dislocation of the lower end of the radius back wards, or, in other words, of the lower end of the bone forwards, the axis kind of pressing, situated in the opposite direction, would serve to accomplish the reduction.—See *Chapman's Clin. & Surg.*, p. 10.

In the fracture of the lower end of the radius forwards, upon the supina, Mr. Astley Cooper effects the reduction, by extending the hand, while the forearm is fixed.—(On *Dislocations*, p. 265.)

REDUCTIONS OF THE WRIST.

The carpal bones may be displaced from the lower side of the radius and ulna forwards or backwards. The case backwards is the most frequent. It is facilitated by the direction of the convex articular surfaces of the scaphoid, lunate, and triquetrum bones, which slope more backwards than forwards. According to Mr. Astley Cooper, the direction of the force determines the direction in which the carpal bones are displaced: thus if a person is falling full on his hand to save himself, and fall upon the palm, a dislocation is produced, the radius and ulna are forced forwards upon the scaphoid ligaments, and the carpal bones are thrown backwards. A considerable swelling is produced by the radius and ulna on the fore part of the wrist, and a similar protuberance upon the back of the wrist by the scaphoid, with a depression above it, and the hand is bent back.

When the carpal bones are dislocated forwards under the lower tendons, and the radius and ulna backwards upon the posterior part of the carpus, the accident has been caused by a fall on the back of the hand.

In both of these cases, two swellings are produced; one by the radius and ulna; the other by the bones of the carpus. Sprains will often cause a good swelling over the dorsal tendons, and give rise to the protuberance of a location, from which they may always be known by the swelling being single, and by not having such an appearance directly after the injury.

Dislocations forwards or backwards are never complete. The protuberance of the carpal bones at the inner or outer side of the joint, and the distortion of the hand, make such cases sufficiently evident.

Several dislocations of the wrist, particularly such as are incomplete, are easy of reduction; but when the dislocation has been suffered to continue some time more difficulty is experienced, and in a few days all attempts are generally unavailing. This observation applies to all dislocations of synovial joints; and I cannot, therefore, too strongly caution the student at such a time to dispose the swellings of the soft parts of the bones are exposed; an absurd plan, which, I am sorry to say, is mentioned by Boyer.—(*Mat. Med.*, v. 4, p. 789.)

For the purpose of reducing the dislocated bones, antiseptic powder must be made, while the two surfaces of the joint are made to slide on each other in a direction necessary to what they took when the accident occurred.

In dislocations of the wrist, numerous blisters are always necessary applied, and many leeches employed; consequently, a good deal of swelling generally follows, and the patient is a long time in regaining the power use of the joint. Hence the propriety of coating, first oil, and opening, nistie medicines; while the hand and wrist should be continuously covered with flannel wet with the decoction of malt, or spirit of wine and water, and the fingers and hand kept in splints, which ought to extend barely to the end of the fingers, so as to prevent a return of the dislocation. The first point also remains quiet to a day.

When the ruptured ligaments have healed, linctures will need to be used the remaining stiffness and weakness of the joint.

REDUCTIONS OF THE WRIST, WITH CALLOSITY, STIFFNESS, AND TENDRIL.

A simple dislocation of the carpal bones from each other seems almost impossible. "The os metacarpale, however, has been known to be partially lacerated from the deep artery formed for it in the os scaphoideum, and os lunate." This displacement is produced by too great a flexion of the bones of the first phalanx on those of the second, and the os metacarpale serves a support on the back of the hand.—(Goussier's *Revue*, *Revue*.)

Chopart also met with a partial laceration of the os

metacarpale in a fracture. "Ramus Boyer has seen several examples of the accident, which, he says, is more common in women than men; a circumstance which is ascribed to the ligaments being looser in females, and to the bones of the carpus in them having naturally a greater degree of mobility. The fracture occurs when the hand is bent, and disappears when it is extended. The case does not produce any serious consequences, if the wrist be extended, and pressure be made on the head of the os metacarpale, the reduction is easily accomplished; though a removal of the displacement would be prevented, unless the extension and compression be kept up by means of a suitable apparatus during the whole time requisite for the healing of the lacerated ligaments. As the loose tendons of the accident are slight, few patients will submit to any tedious, tedious treatment; and sometimes the stygium is never corrected, all it is too late to think of replacing the bone. In general, therefore, he is obliged to be content with limiting the case as a sprain or contusion."

Mr. Astley Cooper has seen two cases of displacement of the os metacarpale in fracture: the accident produced a weakened state of the hand, and upon first relaxation of the ligaments. One example is also given of a dislocation of the os scaphoideum, which was thrown backwards upon the carpus, with the lower part of the broken radius.—(On *Dislocations*, p. 316, 322.) Compound dislocations of the wrist bones are uncommon, and generally arise from gunshot violence, or other great mechanical injury. In these cases, it is sometimes necessary to take away the displaced bone altogether; and too frequently the accident is such as to require amputation.

The connection of the metacarpal bones with the scaphoid, and with those of the carpus, is so close, and the degree of motion so slight, that a dislocation can hardly take place. Thus, Mr. Astley Cooper, in an exact dissection, has never seen them dislocated, except by the tearing of parts, or by the passage of heavy carriages over the hand; cases frequently demanding amputation.—(On *Dislocations*, p. 316.) The first metacarpal bone, which is articulated with the os trapezium, and admits of the protrusion of flexion, extension, abduction, and adduction, is capable of being lacerated; but the accident is uncommon, for reasons explained in my other work.

Although from the nature of the joint, between the first metacarpal bone and the trapezium, one might infer that a dislocation is possible in the four directions, backwards, forwards, upwards, and downwards, yet if we are to believe Boyer, the first case is the only one which has been observed. The accident is produced by the application of external force to the back of the metacarpal bone, which is suddenly and violently driven into a state of flexion, the bone usually coming from a fall on the outer edge of the hand. In this circumstance, the upper end of the bone is forcibly driven backwards, the carpal ligaments is lacerated, and the posterior part of the thumb are pushed up, and the head of the bone slips behind the trapezium.

For an account of the symptoms and treatment of this accident, I must refer to the fifth edition of my *First Lines of the Practice of Surgery*.

The first phalanges of the fingers may be dislocated backwards of the heads of the metacarpal bones. A fracture forwards would be very difficult, if not impossible, because the articular surfaces of the metacarpal bones extend a good way forwards, and the pain of the hand makes resistance to such an attempt. The first phalanx of the thumb is, however, often dislocated backwards behind the head of the first metacarpal bone, in which case it remains extended, while the second phalanx is bent.

These dislocations should be speedily reduced, for after eight or ten days they become irreducible. In a situation of the first bone of the thumb which was one old is usually reduced, and where the pain was shown behind the head of the metacarpal bone, the usual proposed riding down to the dislocation, and pushing the head of the bone into its place with a syringe. Even in cases where one side is bent, this kind of dislocation frequently cannot be reduced without the utmost difficulty; and the dislocation presents which have been most conspicuous in this particular accident, by Mr. Evans, the late Mr. Hey, Mr. C. Hall, and Boyer, demands the action of the surgical practitioner, and will not be cured by any other means.—(On *Dislocations*.)

1861, however, Sir Astley Cooper remarks, that he has seen few such, resulting from direct injury to the bones and ligaments, and he recommends their division, in order to facilitate their reduction, when extension will not succeed.—(*Ibid.* *Dislocation*, p. 322.) Dislocations of the wrist and little finger, thumb, and that of the thumb outward (which are possible cases), and dislocations of the first phalanx of the other fingers backwards, and of their second phalanges forwards, are all subject to being returned on the crown and of the affected thumb or finger, and at the same time pressing the head of the bone towards its natural situation.

After the reduction, the thumb or finger should be secured with tape and surrounded and supported with cotton-wool, the displaced ligaments being exactly cut being taken to keep the hand and forearm in a sling. The fixation of the first phalanx of any thumb behind the intersepal bone, requires peculiar treatment, as I have elsewhere explained.

DISLOCATIONS OF THE BONES OF THE PELVIS.

Experience proves, that the bones of the pelvis, notwithstanding the vast strength of their ligaments, may be dislocated by violence; thus three sacral spurs in a female forwards towards the lateral of the pelvis; the os pubis may be displaced forwards and upwards; and the bones of the pelvis may be totally separated at the symphysis, and an evident degree of mobility, or rather freedom than. For the production of these accidents the operation of enormous force is requisite; and in fact, three usual stories are told of a great height, the fall of a very heavy body against the os pubis, at a period when the body is fixed; and the pressure of one pelvis against a wall or post, and the wheel of a carriage or wagon. Hence, the dislocation is generally the least part of the mischief sustained by such kinds of violence, and the case is necessarily attended with commotion of the spinal marrow, injury of the sacral nerves, extension of blood in the cellular membrane of the pelvis as every of the permanent injury of the uterus, and fracture of one or more of the bones of the pelvis. As Sir A. Cooper has remarked, some of these cases complicated with fracture, are liable to be mistaken for dislocations of the thigh:—"When," says this gentleman, "a fracture of the os pubis occurs, it happens through the acetabulum, the head of the femur is drawn upwards, and the trochanter major moves forwards so that the leg is shortened, and the knee and foot are turned upwards. Each a case, therefore, may be readily mistaken, if the os pubis is separated from the os sacrum, and the os pubis and ischium are broken, the head is slightly turned from the other; but the knee and foot are not turned upwards. These accidents may generally be detected by a rupture perceived in the socket of the thigh, when the os pubis appears bare to the view of the thigh, and there is greater motion than in a dislocation of the thigh."—(*Surgical Remarks*, part I, p. 48.)

In addition to the complications which may attend a dislocation of the bones of the pelvis, and more immediately from the internal violence, the case is always attended by inflammation, which may be very serious, and only in a small amount of the extent of the anterior various affections, the disease such inflammation may extend to the peritoneum and viscera of the abdomen and pelvis, and lastly itself when it has or three weeks.

Little notice a case in which the os ischium of the right side was found separated from the os sacrum as to prevent, nearly three inches behind it. This accident was caused by a heavy sack of wheat falling on a soldier.—(*Ibid.* *Dislocation*, p. 44, 45.)

In a case recorded by Sir A. Cooper, the posterior part of the sacrum was broken off, and the head of the thigh bone had slipped from its socket; the fragments extended across the os pubis towards the os ischium, the bones of which were separated at the symphysis nearly an inch asunder. The os were separated on each side, and the left os pubis, ischium, and os sacrum broken.—(*Surgical Remarks*, part I, p. 48.) In the same work may also be noticed another case of fracture of the body of the os pubis and union of the ischium, sustained with a fracture of the right os ischium from the os sacrum, and fracture of the ischium of the os pubis.

When these cases are not proved fatal from the direct effect of the great violence communicated on every part,

or from peritonitis, the same unpleasant even sometimes follows rather later from separation of the articular surfaces taking place, and abscesses forming in the cellular membrane of the pelvis.—(*Ibid.* *Dislocation*, p. 44, p. 117.)

A case in which a dislocation of the left os ischium upwards had a successful termination, was attended by Lewis, Hunt, and Chamberlain, and is published in a modern work.—(*Ann. de l'Hôtel des Malades de Paris*). As the reduction could not be effected, and at first, antiphlogistic treatment was followed for some days, when more attempts to replace the bone were made, but could not be continued, as they caused a recurrence of such and other bad symptoms. A third trial, made at a later period, was not more efficacious; and all thoughts of reduction were then abandoned. After the patient had been kept quiet some time, though not as long as was wanted, he gained his bed and began to walk about on crutches. I do not understand, however, as it is asserted, how the weight of the body could now bring about the reduction, which had been previously attempted in vain. In this last way, the result was the patient's recovery. The fact clearly proves, as Boyer observes, that in cases of this description the most important object is not to aim at the reduction, but rather to oppose, by every means in our power, inflammation and its consequences. Properly the use of the caustic is necessary, and expression as immediate of urine, or the salutary discharge of the feces, demands the strictest attention to cleanliness. In these cases, if the patient live any time, there is also another source of danger, consisting in a tendency according to the soft parts, on which the patient lies, and which, when they have been bruised, require still greater vigilance.

The os coccygis is not so easily dislocated as first stated. Boyer has seen it displaced in a man who was greatly distressed by disease. This subject had considerable distress about the coccyx, and the bone itself was torn. There was an interspace of nearly two inches between the os sacrum and base of the coccyx. In proportion as the tumor increased in size, the bone reappeared in this position, and at length united to the os sacrum, notwithstanding the action of the levers and oil, which are inserted into it. This case, however, was not an accidental fracture, and it clearly arose from the destruction of the ligaments by disease.

Authors mention two kinds of dislocation, to which the os coccygis is liable; one upwards, the other downwards. The first is always connected by external violence; the second by the pressure of the pelvis itself in difficult labors. First, difficulty of making the knee and thigh move, and sometimes even, sometimes violent in disease which attend the pelvis, are symptoms said to attend and follow dislocations of the coccyx.

The best authors have regard also to the reduction, as well as the bone with spontaneously return into its place as soon as the cause of displacement ceases; and the introduction of the finger within the rectum, and handling of the perineal and internal parts, are more likely to increase and obstruct inflammation, and produce abscesses, than have any beneficial effect. In short, the usual plan is to be content with exposing quickly, and adopting antiphlogistic measures.

DISLOCATION OF THE KNEE.

J. K. Parr was silent on this subject, as he thought such cases never occurred. Since his death, a French surgeon, Bistart, has treated an instance which is supposed to be a dislocation of the posterior extremity of the tibia from the femur. Sir Boyer clearly proves, that there were no true reasons for this opinion, and that the case was only a fracture of the neck or head of the bone near the spine.—(*Traité de Mal. Chir.* p. 4, p. 224.)

Andrew Parr, Easton, Jüncher, Pott, and Hunter not only affirm the occurrence of luxations of the knee, but describe different species of them. Lankford also extended the term *luxation* to cases in which the head of the tibia separated by disease, the process of anastomosis, &c.

In a recent work, may be read the particulars of a case where all the ribs are said to have been dislocated from their articulations. The accident arose from the chest being violently compressed between the beam of

a stiff and the weak. In such a case there is no reason of reduction except the effort produced by forcible compression; nor are there any modes of relief but bleeding, and the application of a plaster round the chest. — (See C. Holt's Surg. (3d. p. 171.)

DISLOCATIONS OF THE THIGH-BONE.

The head of the thigh-bone may be dislocated upwards in any direction of the acetabulum; upwards and forwards on the body of the acetabulum; downwards and forwards on the femoral oval; and backwards on the ischial notch.

The dislocations upwards and that downwards and forwards, are the most frequent.

The dislocation of the thigh-bone upwards on the lesser of the lesser is attended with the following symptoms. The limb is from one inch and a half to two inches and a half elevated from its fellow, the thigh a little bent and carried forwards. The knee inclines more backwards and upwards than the opposite one; the leg and thigh are turned forwards, and the foot points in the direction; the toe resting, as Sir A. Cooper remarks, against the tarsus of the other foot. — (Surgical Essays, part 4. p. 25.) There is an approximation of the trochanter major to the anterior superior iliac spine, and the thigh, and at the same time it is elevated and carried a little forwards. It is also less prominent than that on the opposite side, and the painful resistance of the hip is less dependent. The natural length of the limb cannot be restored without reducing the fracture; the foot cannot be turned upwards, nor any attempt to do so causes pain; but the inclination of the foot upwards may be increased. — (Ibid.)

When attempts are made to draw the thigh away from the other, it cannot be accomplished. But the thigh may be slightly bent across its fellow.

A dislocation of the lesser of the lesser is generally at once readily discriminated, from a fracture of the neck of the thigh-bone, within the capsular ligament, by the position of the limb upwards, a position which is unusual in a fracture of any part of the os femoris.

In a fracture of the neck of the thigh-bone (says Sir A. Cooper) the knee and foot are generally turned upwards; the trochanter is drawn backwards; the limb can be readily bent towards the adductor, although without pain; but, always, the limb which is shortened from one to two inches by the contraction of the muscles, can be made of the length of the other by a slight extension; and when the hip-joint is observed the leg is again shortened. It when extended, the limb is raised, a crease can often be felt, which arises when rotation is performed, under a shortening of the limb. The fractured neck of the thigh-bone, within the capsular ligament, rarely occurs but is advanced age, and it is the effect of the most trifling accident; owing to the absorption which takes place of the bone trabeculae at advanced periods of life. Fractures external to the capsular ligament occur at any age, but generally in the middle periods of life; and these are easily distinguished by the creases which attend them, if the limb is rotated and the trochanter is commensurate with the head. The position is the same as in fractures within the ligament. The proportion of fracture of the neck of the thigh-bone which I have met, is at least four cases to one of dislocation. — (A. Cooper, Surg. Essays, part 4. p. 28.)

The position of the limb upwards, in most of fractures of the neck of the thigh-bone, is temporary, though sometimes not so. Sir A. Cooper gives one example of it, under the name of Mr. Langstaff — (On Fractures, Preface). To reduce this dislocation, the patient should be placed on his opposite side upon a table firmly fixed, on a large four-posted bedstead. A cloth being judiciously to be so placed under the hip-joint, and the limb being carried below the patient, the other limb then they put so be fastened to one of the four posts of the bed. Then the patient will be fixed, so as to allow the necessary extension of the thigh-bone to be made. About nine inches may be taken during the extension to keep the screws and needles, or the needles in women, from being torn by the muscle passed under the peritæum. The patient may be then fixed by the assistant.

The best position of the patient may be placed against the extending force to be applied to the inferior part of the leg, in order that it may be as far as possible from the parts which resist the return of the head of

the bone into its natural situation. In this country surgeons generally make the extension by means of a sheet, or the strap of a pulley, attached round the limb, just above the ensilage of the os femoris. The direction in which Sir A. Cooper makes the extension is at the knee made by the table, when it is brought across the other thigh a little above the knee. As soon as the head of the bone has been brought on a level with the acetabulum by the assistants who are holding the extension, the surgeon is to take it up this way by pressing on the great trochanter, it is raising the knee and foot gently outwards, as practised by Sir A. Cooper.

The extension should always be made in a gradual and increasing manner; at first gently, but afterwards more strongly; never violently. The efficacy of reduction arises from the great power and resistance of the muscles, especially the psoas and iliacus, which will at length be relaxed, so as to yield to the extending force, if once it is taken that it is recognized the necessary time, without the least intermission. Sometimes, when there is difficulty in bringing the head of the bone over the lip of the acetabulum, Sir A. Cooper raises it by placing his arm under it and the joint.

The Government of all the symptoms, and the same made by the head of the bone when it is up into the acetabulum, ensure that the reduction is effected. Therefore, however, is not always made when patients are used. The table is afterwards to be kept from slipping out again, by tying the patient's knees together with a bandage placed a little above the knee. The patient should be kept in bed at least three weeks. The joint, and with the joint with a compress over it. The treatment to be given by the reduced ligaments is usual, and the exposed joint is covered. The patient may be fixed on a four-posted bedstead by Sir A. Cooper.

Mr. Key gives the following description of the way in which he reduced a case of this kind.

"The extension of the limb must be made in a right line with the trunk of the body; and, during the extension, the head of the bone must be directed upwards as well as downwards. A temporary traction of the os femoris as the arm is, towards the knee (the patient lying prone), seems likely to facilitate the great trochanter, being it returns to its natural position, and draw the head of the bone towards the acetabulum. These circumstances led to the following method: a folded blanket was wrapped round one of the bed-posts, so that the patient, lying in a prone position, and astride of the bed-post, might have the affected limb on the outside of the bed. The bed was raised immediately by placing it against a small iron pillar, which had been fixed for the purpose of supporting the curtains. The leg was bent to a right angle with the thigh, and was supported in that position by Mr. Lamb, who, when the extension should be brought to a proper degree, was to give the thigh its ordinary motion, by pushing the leg forwards; that is, towards the other femoral extremity. Mr. Lamb sat before the patient's knee, and was to assist in giving the necessary motion, by pushing the knee outwards in the same direction. I sat by the side of the patient, to raise the head of the bone downwards, and upwards during the extension. Two long towels were wrapped round the thigh, and above the crutches; one lower passing on the front of the knee the other on the situation. These towels made the extension, but when we attempted to give the thigh its ordinary motion, we found it resisted by the towels, which passed on the inside of the knee and leg. We therefore passed both the towels on the outside; and in this position, the extension was continued as given the ordinary motion. The first effect was relaxation of the bowels; were this passed, and the desired effect, and the head of the bone moved downwards and upwards into the acetabulum. — (Phys. Journal Observations, p. 202.)

For the purpose of dissolving the osseous, and the osseous callus to produce a permanent fixation by a osseous connection, immediately after the reduction is made, a practice which, when the general state of health does not forbid it, is advisable, as it offers very materially the resistance of the muscles. Sir A. Cooper gives a full practical application, as well as the waste bath, and subsequent doses of tartaric acid. Afterward, every four hours to twenty drops of blood; this gentleman gives the patient a

both heated to 130 degrees, and gradually raised to 11 degrees, until fermentation started. When in the bath, the fermenter is also to take a grain of tartaric acid every ten minutes, until several ounces will fit in as it is removed from the bath, put in three lots, and raised between 190 and 200 degrees, or say, on which a sample is made; it is ready to be placed on its side, into which two rings may be inserted. The mixture is ready for B. Coker, performed the commonest work, and by making the various sorts of flour, sugar, etc., having been denied in the name of the *First House of Society*. I had one last experience. Of Mr. Hays's part, especially the director of the bank of it, is important as a scientific opinion on little published, is known where the reduction has been at 200 and 170. (The *First House*, p. 10.) In the middle, it is fully in order. Each part of distillation, the above mentioned in distillation process, the increasing of heat of which is the same, and the water in the top, or the top of the vessel, is put to the water in the bottom.

[illegible][illegible][illegible][illegible]

Mr. HAY said, that "in this system of education (distributing and circulating, on the basis of the laws of Yon. 1-8

extended lower than the acromion, that is, on a level that is a right line with the neck. A right line must extend the head of the bone further from its proper place, and directly present, instead of ascending, elevation. The extension ought to be made with the right at a right angle, to include something less than a right angle in the trunk of the body. When the extension has removed the head of the bone from the natural oblique direction, which covers the great femoral artery, the supinator, the upper part of the os humeri must then be put in a direct position; which end will be greatly assisted by moving the lower part of the os humeri, in the same manner, in a contrary direction; and, by a rotatory motion at the same time, its crest will, turning the head of the bone towards the acromion." (Ibid., p. 216)

The wooden fence illustrates Mr. Hay's policy. The fence post, on the right side of the fence, which the nation left, was placed in contact with a small immovable iron plate (about an inch square) in Dickinson, which is the only stone used for supporting the fence-post of the fence. A barbed wire is wrapped round the fence post and plate, the present was placed outside of them, with the left hand close to the post, and his right hand on the outside of the fence. It takes some of the fence wire and beyond the market and the fence, that the fence post be kept during the election.

The patient sat upright with his shoulders in contact with the golden handles which curved the bedpost. He appeared relaxed by putting his arms about the post, and as I passed he turned him to look at me from reading backwards. He was also squirmed in each side.

Two half-owls were put around the lower part of the thigh, after the part had been well defended from excretion by the application of a tannic rubric. The hind wife in the lower form was made upon the anterior part of the thigh, and the cranium extended to be green to the eye might not be attacked by the disease.

The things being played is a horizontal position, or rather a little advanced, with the leg hanging down at right angles to the thigh. I put down upon a chair the two opposite patients, and directed a gentle traction to be made by the assistants standing on my left side. This was done with the view of drawing the head of the bone a little nearer to the middle of the thigh, and the extension had this effect. I then joined the two assistants who held the middle of my right side, by which means the extension would be made in a direction a little inclined to the vertical line. Mr. Loper stood on the right side of the patient, with his hands placed on the upper and lower side of the thigh, for the purpose of drawing the head of the bone nearer the acetabulum, when the extension should have been continued, until the bone came into its place.

I desired the assistants to make the extension slowly and gradually, and to give a "rest" when it arrived at its greatest degree. At that moment Mr. Logan drew the upper part of the body upwards, while I pushed the lower upwards, and used just the 60 pounds a considerable muscular tension, by pushing the right leg upwards the left. By these combined motions, the head of the 60 pounds was thrown upwards, and upwards, up, in other words, directly towards the horizontal, and which it covered as our first attempt made in this manner. (MS. A, 218.)

[illegible]

In the context of The purposes of the book, however, it seems fairly clear, and the opposite to what Boyer has said, on A's second remarks, that there is a sign, namely, a vowel and syllable. — (Surgical Knowledge, 1.1.1.35.)

The head of the bone felt in the grain, and the face

In such cases, if there be no previous morbid relaxation of the parts, a portion of the capsular ligament will be torn. (A. Cooper, on Dislocations, &c. p. 176.) The generality of cases are easily relieved by pressure when the extension of the leg have been completely relaxed; but owing to a lax state of the ligament of the patella or other predisposing causes, the bone is sometimes actually kept in its proper situation, unless a roller is applied. The dislocatory action of the joint is to be opposed by steadily pulling, and the use of the loco flexor instruments. The joint must be kept quiet a few days, and then gently moved in order to prevent stiffness. When the anatomical situation is such that a relapse is likely to occur, they should be kept in a fixed position, with a strap and bandage above and below the patella, should be worn as recommended by Sir Astley Cooper—(On Dislocation, p. 76.) The location of the patella upwards, gives a figure of an ligament, is a case followed by a considerable degree of inflammation. Hence Sir Astley Cooper particularly recommends early depletion; the use of evaporating lotions from four to seven days, and then a roller to the foot and leg. The leg is to be kept extended by means of a spiral behind the knee; a double strap is to be buckled round the lower part of the thigh, and so on, on each side, another is buckled, which extends from the side of the foot, and is carried up each side of the leg. Thus the patella is kept down, and an apparatus is applied for the ligament to unite. In a month, the knee will be gradually moved every day.—(On Dislocations, p. 302.)

DISLOCATION OF THE KNEE.

The tibia may be thrust forwards, backwards, or to either side. As Boyer observes, complete dislocations of the upper end of the femur are extremely rare, because the anterior surface of the condyle of the femur is so extensive that the tibia cannot be thrust forward from it without a prodigious laceration of the ligaments, tendons, and all the rest of the soft parts.

The condyles of the femur are disposed in such a manner, that, in the extreme flexion of the leg, the anterior surface of the upper end of the tibia are still in contact with these bony surfaces; and this circumstance, together with the resistance made by the ligament of the patella, the patella itself, and the tendons of the extensor muscles of the leg, renders a sudden dislocation of the tibia backwards so difficult, that Boyer seems even to question the possibility of the accident, notwithstanding the case related by Hunter.—(Treatise on the Fracture, &c. p. 205.) This dislocation, however, sometimes really happens, not large amounts of ligaments: the case is related by Sir A. Cooper as producing the following appearances; a charred state of the limb; a protrusion of the condyle of the femur; a dislocation in the situation of the ligament of the patella; and a swelling of the leg upwards; which last situation differs from that of Boyer, who declares that the leg is bent to a very great degree, and cannot be extended again.—(Med. Chir. &c. p. 201.) It appears further, from the particulars of the example of this dislocation, given by Dr. Williams, that the dislocation appears to complete the bend of the tibia during flexion instead of the condyle of the femur into the knee. The tendons connected of the patella to the femur muscle was ruptured, and, probably, not only separated of one tendon, all of the ligaments of the patella, and a considerable amount of the muscles have lacerated.—(Surg. and Anst., vol. 2, p. 78.)

But if a sudden dislocation of the tibia from the femur backwards is impossible, the same remark cannot be made respecting a dislocation, in that direction, gradually produced by the effects of disease. Several cases of the latter kind have fallen under my own observation.

A dislocation of the head of the tibia forwards, from the condyle of the femur, cannot happen without the greatest difficulty, or the accident would be likely to be attended with laceration of the lateral ligament, and other, or posterior ligaments, all which need to convert the leg from being too far extended; and, in addition to all this injury, Boyer calculates that the head of the gastrocnemius, the popliteus, and the posterior tendons of the leg, would be immediately ruptured, and even torn. However, it does not seem that it is one complete fixation of the knee, when the anterior part of the tibia has been thrust into the space of the head

of the tibia, the external condyle being dislocated backwards and upwards, and the internal one thrown forwards upon the head of the tibia, the dislocation proved that "scarcely the osseous surface, the popliteal artery and vein, the lateral, nor the crucial ligaments were ruptured."—(A. Cooper, on Dislocations, p. 197.) Both bones of the gastrocnemius were lacerated, and the back portion of the capsule, ligament, extremely torn. In 1802, an instance of a laceration of the tibia upwards was seen at Gay's Hospital. According to Sir Astley Cooper, while the tibia projects forwards the dislocation is supposed, and driven somewhat laterally as well as backwards. The os femoris makes great pressure on the popliteal artery, as to prevent the pulsation of the anterior tibial artery on the tibia; and the patella and tibia are drawn forwards by the rectus quadratus.—(Surgical Essays, part 2, p. 72.)

Dislocations forwards or upwards, though more frequent than the foregoing ones, are still to be considered as rare, and are always incomplete. In the dislocation forwards, the condyle of the os femoris is thrust upon the external malleolus, cartilage, and the tibia projects in the lateral side of the foot, so as to cause to dislocate the nature of the accident; and a depression may be felt under the external condyle. In the dislocation of the head of the tibia upwards, the condyle of the os femoris is thrust upon the tibia, sometimes cartilage, or, under Sir Astley Cooper says, rather behind it.

In both these cases, this position, though that the tibia is rather thrust upon the os femoris, so that the condyle of the latter bone is thrust somewhat back, worse as well as upwards or inwards.

I have stated that lateral locations of the tibia from the femur are always incomplete; but the possibility of a complete dislocation upwards seems to be established by the third case, of LACROIX.

Whenever the tibia is dislocated from the femur, the accident has generally happened either while some force was exerted upon that bone, at a period when the tibia was fixed just immovably, or else while the tibia was, as projected, or thrust with great violence, while the leg itself was freely fixed.

These accidents are all necessarily relieved by making proper extension, and placing the head of the tibia in the proper position. The great object, after the reduction, is to avert inflammation of the knee, and possibly the rupture of the ligaments. The first remedies the rigidity, immobility of the articulation, pain—bleeding, leeches, low diet, opening medicines, and a cooling evaporating lotion; both require the limb to remain perfectly immovable. With respect to splints, I observe that their position would be objectionable. As soon as the ligaments have grown together, and the danger of inflammation is over, which will be in about three weeks, the limb should be gently bent and extended every day, in order to prevent stiffness. Treatments will now also be of service.

In the next, we must consider the cases which were first described by the late Mr. Hey, and are named by Sir A. Cooper partial luxations of the thigh bone from the acetabulum cartilages. Mr. Hey observes, that the dislocation may happen either with or without resistance. When no resistance has occurred, or the effects of it are removed, the joint, with respect to shape, appears unaltered. If there is any difference from its usual appearance, it is that the ligament of the patella seems rather more relaxed than that of the sound limb. The leg is usually loose, or extendible by the hands of the surgeon, and without pain in the patient; or, at most, the degree of tenderness caused by the fluxion and extension is trifling. But the patient himself cannot freely bend, nor perfectly extend the limb in walking; and he is a great deal to walk with an irritable and small degree of lameness. Yet though the leg is stiff in walking, it may be freely moved while the patient is sitting down.

Mr. Hey notices this complaint to be a disease which had the effect of breaking the condyle of the os femoris from having truly is the hollow formed by the acetabulum, cartilages, and articular depression of the tibia; or, at least, a laceration of the lateral or crucial ligaments; or some slight detachment of the osseous cartilages.—(Phil. Chir. p. 322, et. 2.) Sir A. Cooper says, the most frequent cause of the accident is the point of the foot, while pressed, striking against any projection, which joint is immediately felt in the knee, and the patient becomes incapable of perfectly extend-

where there is dislocation of the distal extremity at the proximal end, writers have done, in this it should be named a *dislocation of the distal extremity*, or, at least, the direction in which the dislocation is carried.—(Gosselin, *Med. Chir.* p. 3, 1855.)

With respect to the treatment of the preceding case, Dupuytren admits, that Pott's method, easily effects a reduction, though complete or permanent; it, but, as I have ascertained in practice in the last edition of the *First Lesson of Surgery*, the practice recently proposed at the Hôtel-Dieu, it would be useless repetition to enter into the subject again. Mr. A. Cooper appears to prefer the rule of treatment as Mr. Pott's principle; but gives no very essential point of advice, which is, that the splint upon which the upper part of the limb must rest have a fulcrum, "to give support to the foot, prevent its eversion, and preserve it at right angles with the leg." It must be understood, however, in case it is to be applied to the parts, and the connection, and require relief by taking band from the arm?—(Surgical Essays, part 2, p. 116.)

When the tibia is dislocated *outwards*, the internal lateral ligaments are usually ruptured, or pulled away from the bone, and the outer malleolus broken away from its fracture of the tibia. As a part of this, sometimes, however, Dupuytren and Mr. A. Cooper differ, as the latter asserts that the dislocated tibia is broken. In many cases, he says, the fracture is not confined to the malleolus, the tibia is broken through the anterior border of the tibia, which is directed forwards and outwards upon the malleolus, in front of the malleolus. Sometimes the malleolus is fractured, and the lower extremity of the tibia broken into several splinters. He maintains, that when the tibia is in this position, the external lateral ligaments are ruptured. The foot is thrown outwards, the outer edge resting upon the ground, while a considerable protrusion is made by the malleolus coming under the skin. The position is generally caused by the patient, or a wheel of a carriage over the leg, or a violent blow at the foot forwards in jumping or falling.—(J. Cooper, ed. 4th, p. 112.)

The reduction is accomplished by relaxing the tension of the calf, making extension to the axis of the leg, and passing the lower end of the tibia forwards towards the malleolus. "The tibia is to be laid upon its inner side, resting upon a splint with a foot piece, and a pulley to be placed opposite the tibia just above the outer angle, and extending a few inches upwards, so as to secure extension to raise that portion of the leg, and prevent the tibia and tibia slipping over the malleolus, as well as to lessen the pressure of the soft parts on the malleolus upon the malleolus."—(Surg. Essays, part 2, p. 112.) Mr. A. Cooper also advises giving the external rotation to the foot, the foot being placed outwards as possible downwards.

Dupuytren's manner of treating this case is described in the last edition of the *First Lesson of Surgery*.

A complete dislocation of the lower end of the tibia forwards seldom happens without the tibia being first broken, and either the base of the malleolus internal fractured, or its part torn away. The foot being thus laid upon by the external and lower malleolus, and sustained by the malleolus and ligaments, while the powerful contracture of the muscles of the calf, the malleolus passing behind the tibia, while this projects forwards under the tibia and distal of the tibia.—(Dupuytren, *Art. de Chir.* p. 287, 4th Paris, 1813.) The foot of course is much shortened, the heel protruding, and firmly fixed, and the toes point downwards. Upon dissection, the tibia is found to rest upon the upper portion of the os pubis, and on the condyle of the femur. The anterior part of the os pubis is injured is less through; the distal ligament is only partially lacerated; and the three ligaments of the tibia remain attached.—(J. Cooper, ed. 4th, p. 110.)

This case is really more difficult of reduction than the tibia in which the foot is thrown outwards, and the cause is owing to the powerful contracture in which the muscles retain the extension of the parts, and placing them in their natural position again. As Dupuytren observes, it is true that such resistance may be lessened by relaxing the muscles, and drawing the patient's attention from his limbs; place, which fully answers for the relaxation of the other above-mentioned muscles, yet, in that case, the resistance, they are so

stiffened, and here a greater effort is required in being the foot thrown forwards, and to place the malleolus under the tibia. And a still greater difficulty is to keep the parts reduced during the time necessary for the tibia and malleolus to be firmly united. As far, the upper surface of the malleolus, which is convex from behind forwards, is so great, that it is hard to make the tibia rest securely on the anterior surface of that bone, which at last necessarily lies upon by the extreme process of the leg, as it is to have a tendency to slip behind the lower end of the tibia. In addition, therefore, in the last position, Dupuytren shows a necessary belt to require an apparatus, which supports the foot forwards, and the upper end of the tibia backwards.—(Gosselin, *Med. Chir.* p. 185.) As this apparatus has been described in the last edition of the *First Lesson of Surgery*, I need not explain it again.

Mr. A. Cooper prefers keeping the foot upon the foot, resting upon a pulley. A splint, with a suitable pad and a foot-piece, is to be applied to each side of the leg, care being taken to keep the foot well supported at a right angle with the leg.—(Surgical Essays, part 2, p. 116.)

Besides the complete dislocation of the tibia forwards, a partial one is sometimes met with, where one half of the articular surface of the bone has separated or separated, and the other to the malleolus. According to Mr. A. Cooper, the tibia is broken; the foot appears to be dislocated; and there is some considerable protrusion of the foot. The foot points downwards, it cannot be put flat on the ground, and is weakly stiff, and the foot continues drawn up. The reduction, if not detected and reduced in its early stage, attended with a great deal of pain, the change in the position of the muscles, and the position in which the tibia has moved, no ordinary any resistance, even though great force be employed.

Dislocation of the tibia, forwards backwards, and not upwards, during infancy, Dupuytren has observed, but with this is three cases; though he has seen some instances of lateral dislocation. It must be obvious to every body, says he, that when the tibia is violently bent, or extended, many powerful tendons resist the dislocation, in question, and prevent the success with which the reduction is effected.—(Gosselin, *Med. Chir.* p. 185, 4th Paris, p. 28.) A fracture of the tibia from the malleolus backwards, Mr. A. Cooper has never had an opportunity of observing; a proof of the rarity of the accident.

A dislocation of the malleolus, either simple or complicated with a dislocation of the tibia, as Mr. Hey has remarked, is an accident which does not often occur. Above, the malleolus is articulated with the tibia and fibula; below, it is united by means of a capsule ligament, to the os calcis; while in front, it is connected to the os calcis by a superior and broad internal lateral ligament. Thus situated, it is evident that its dislocation is not likely to happen with great frequency; and yet this observation must be received only as a conjecture; for the cases of dislocation of the malleolus, are never noted, or rather ascertained.

When a dislocation of the lower end of the tibia is combined with one of the malleolus from the os calcis and os navicularis, and the ligaments which keep these bones together are usually destroyed, while a considerable portion of the os calcis itself protrudes through the wound in the malleolus, it is no judged prudent to attempt the preservation of the tibia, it is better perhaps to incise the tibia, Pott, Trye, and Keene, and extract the malleolus altogether.

A fracture of the malleolus, attended with a wound in the skin, is a serious and embarrassing accident; for, in general, the reduction is so difficult, that it is not every year where the case was desired a good deal of assistance.—(Gosselin, *Med. Chir.* p. 185, 4th Paris, p. 28.) While the dislocation is in question, the malleolus is gradually thrown forwards upon the os calcis, forming a hump on the inner and bulging a little over to the outer or outer side of the foot. In many cases of this dislocation, the reduction is found to be impossible. Here, as Pott observes, the reduction does not depend upon the head of the bone being contracted in the narrow opening of the capsule; but rather upon the impossibility of making it a solid body, from the pressure of the ligaments.

infected cases in the writings of Lushington, Gault & Chalmers, Tronchese, and other authors of the nineteenth and twentieth centuries. Among Lushington has given the appearance of layers with circles in a fungus in most of the dura mater. The swelling occurred in a short night, years old, was not accompanied, two days after an opening had been made in it.—(Gault, *S. vol. 5, 5*.) Another curious case which happened in a child, and the notes of Chalmers & Gault, is cited as a singular body formation.—(Lushington, *Tronchese*, *vol. 2*, *vol. 6*, 1857, *vol. 28*.) Lastly, Chalmers, a physician of Montpellier, has recorded the history of a lady who died from the consequences of a fungous tumor of the dura mater. The disease was so much pressing, as to interrupt the period of pregnancy. The swelling was covered with crusts. Post-mortem, a fungus was seen, resembling the fungus to be described, but its effect was overruled. After death a fungus of the dura mater, with a perforation in the skull, was observed, but it is described by the author as a hard, very substance, accompanied with pus and infection.—(Chalmers, *vol. 13*, p. 45. See Lushington, *Tronchese*, *vol. 1*, p. 45, *vol. 1850*.)

Several surgeons, greatest of the real character of fungous tumors of the dura mater, used often to take, not the main tumor, and false swellings as the brain, but the disease was of a chronic nature, and made their appearance gradually, in the form of a tumor, which makes its way through the bones of the cranium, often by, and immediately blends itself with the integuments, which show, as if were, to make a part of it. Fungous tumors of the dura mater may sometimes spontaneously in any part of the membrane, but they are particularly apt to grow on the walls, which extend to the upper part of the skull, or to the sides. They are firm, reddish, and chronic, sometimes as if they were the substance of the brain, sometimes, affecting the vessels, which supply the dura mater, and frequently with those of the brain. It is very difficult, one might say impossible, to determine whether, in an instance of this kind, the fungus belongs to the dura mater or the substance of the brain tissue. The general belief, however, is that the tumor is situated on the skull, and that the disease originates in the dura mater. The patient, who is the subject of the first case, stated as a matter by M. Louis, had noticed on the side of the head, and could only trace the origin to a small which he had had with him for five months previously, and in which the head itself had not received any violence; but from this time he experienced a burning sensation, which continued till he died. The covering and dura mater were found both equally diseased. Though this case may tend to prove that fungus tumors of the dura mater only form spontaneously, yet it is not less confirmed by the explanation of a vast number of cases, that this affection more frequently follows blows on the head, than any other cause. Hence a slow kind of inflammation of the dura mater is produced, which ends in a constant effusion, the duration of which always precedes the destruction of the bone. In the memoir published by M. Louis in the fifth volume, first of those of the *Revue Médicale de Vaugy*, there is a very interesting case, illustrating the facts of the present disease.

The subject was a young man, aged twenty-one, who had a considerable tumor on the left side of the head, which was taken for a dermoid tumor.—(See the article.) The swelling had begun in the region of the temple, and had gradually acquired the magnitude of a walnut head. The external car was displaced by it, and pushed down as low as the angle of the lower jaw. At the inner part of the circumference of the base of the tumor the compliances of the perfected tumor and the pulsations of the brain could be distinctly felt. Some parts of the tumor were white and hard, others were soft and fluctuating. A plaster which had been applied brought on a suppuration at some points, from which an infected matter was discharged. Swellings and throbs again and again, and the case died in a few days from the effects of the disease. The disease was a carcinoma of the dura mater, which had been excited, perhaps, by a contusion of the whole portion of the skull corresponding to the extent of the disease.

When a fracture of the bone has already occurred, it makes its way externally through the parts soft or hard which are opposed to it. The swelling, in low-

ering circumstances, is partly bleeded with the dura mater, and its pressure produces an absorption of such parts of the skull as occur in its enlargement. It consequently attacks the skull externally, continuing itself with the scalp, and presents itself externally in the form of a preternatural, soft, swelling swelling, which may sometimes be very apparent, or a third absorption or a pulsation which may make it be mistaken for an aneurismal tumor. When over the swelling has made its way from the cavity of the cranium, it expands on every side under the integuments, which readily make way for its growth. The scalp becomes distended, smooth, and indurated over the extent of the tumor, and slowly it elevates. The tumor disengages from the integuments in thin and soft layers; the outer part of the tumor is embedded with the integuments, and when the skull is which it rests, so that in this state it is not to mistake the tumor for one which has a solid base. While the swelling thus increases it was externally, it may enlarge internally. The latter change takes place in parts, while the opening in the cranium is not large enough to admit the whole mass of the tumor, which then depresses the brain, and before it is contained within it forms a shell. But this slowly quickly disengages, and becomes soft and moist to the touch, as soon as the tumor projects externally. The tables of the skull are absorbed to the swelling arises externally, but it is remarked, that the tumor or fungus always spreads much more extensively destroyed than the external one. Sometimes new bony matter is found deposited around the opening in the cranium.

It is asserted, that whatever may be the situation of a fungus tumor of the dura mater, the outer axis of the membrane, upon which the disease begins, is alone exposed, the inner layer and the pia mater being always protected.—(Lushington, *Tronchese*, *vol. 1*, p. 30, *vol. 1850*.)

In one of these cases, detailed by Walther, the outer layer of the dura mater was quite normal, though the half of the tumor, which was very large, was within the skull, where it had formed for itself a deep excavation in the posterior side of the brain. And, what is remarkable, notwithstanding this large change, the patient, the Mary below her death, retained all her intellectual faculties, and the power of voluntary motion.—(Lushington, *Tronchese*, *vol. 1*, p. 30, *vol. 1850*.)

According to various writers, fungus tumors of the dura mater have been related by continuous as the skull falls on the vertebra, crumpling of the head or whole body; that vertebra, vertebra, vertebra, vertebra, &c. The three last of the alleged causes, however, seems to be little better than mere conjecture; and the same may be said of Walther's idea, that the disease is of a similar nature to white swelling of the lungs.—(Lushington, *Tronchese*, *vol. 1*, p. 30, *vol. 1850*.)

Even children of the most tender years are liable to the disease. M. Louis has related, that a child two years of age, had a fungus of the dura mater, which had produced a swelling above the right ear, attended with a fluctuation of a portion of the parietal and temporal bones.—(M. Louis, *Revue Médicale de Vaugy*, *vol. 5*, *vol. 21*.)

Though the common opinion is, that these fungi grow slowly, than the dura mater, however, some cases that the vessels of the dura have a considerable share in their production.—(Lushington, *Tronchese*, *vol. 1*, p. 30, *vol. 1850*.)

A similar belief was entertained by Boerhaave and Kestner, and is repeated by Walther and Walther, the latter attributing the disease to a direct action of the vessels of the dura mater and pericranium, attended with an absorption of the bony part of the bone.—(Lushington, *Tronchese*, *vol. 1*, p. 30, *vol. 1850*.)

The existence of a fungus tumor of the dura mater cannot be ascertained, so long as there is no external change. The effects produced may arise from many causes, that there would be great risk of a false mistake in relation to any particular case. This is not the case when there is an opening in the skull. Then a fungus tumor of the dura mater is the cause of the disease, because that it comes from within. When the swelling is externally limited, such a resolution is perceived, as when the tumor

tending dry pockmarked effluvia over the skin. On feeling with extreme pain is commenced, and sometimes a numbness in all the limbs, stupor, and other more or less alarming symptoms. The tumour is some measure rounder, less hard, especially when suit very large, and gradually runs up and downwards again. When the pressure is discontinued. Sometimes there is pain; at other times there is none, which may be owing to the manner in which the tumour is affected by the edges of the bone through which it passes. The pain is often made to go off by compression, but returns as soon as this is taken off. The tumour has an alternate motion, derived from the pulsation of the brain, or of the large arteries at its base. This throbbing motion has led many practitioners to mistake this disease for an aneurism, as happened in the second case related in the memoir of M. Louis. When the tumour is pushed sideways, and the finger carried between it and the edge of the bone, through which the tumour protrudes, the bony edge may be felt touching the base of the swelling, and much at one contracting it. This symptom, when feeling is able, added to a certain hardness and elasticity, and sometimes a faintly of pulsation, forms a pathognomonic mark, whereby fungus haemorrhoides of the dura mater may be discriminated from hernia of the brain, exterior fleshy tumours, aneurisms, cysts, and other effluvia which at first resemble them.

Probably, however, some variety in the symptoms prevails in different instances; for in the cases recorded by Walther there was no pulsation, nearly as called, but merely an obscure movement, or an alternate dilatation and contraction, arising from the influx of blood into the vessels of the diseased part: for tumours could not be so far from within the cranium, in the slightest degree; nor did the attempt close any of the effects usually observed to proceed from pressure on the brain. No pulsation could be felt in the neck, much less could the irregular edges of the bone around the tumour be distinguished. — *Ann. der Chir. & B. 1. p. 25—31, 57, 58. Berlin, 1826.*

Whatever tumours also were perceptible in the swelling. Walther is convinced could not be distinguished from them by the pulsation of the vertebral artery; because they were judged, as it were, as an aperture in the skull, and adherent to the dura mater beneath them, and to the superjacent pericranium, so that even in the dead subject they did not admit of being pushed at the least, more forwards without difficulty, and the employment of strong pressure. (Ibid. c. p. 57.)

Indeed, this tight connection of the tumour with the capsule, why suppose, perhaps, it was not brought on in these particular examples by external pressure, but also why the edges of the bone in which could not be felt; and the small size of the swelling, in relation to the magnitude of the swelling, being aneurism, in my opinion, for the swelling's not sinking towards under pressure. But I am far from being satisfied, with Walther, that force of the dura mater are in their nature always irreducible (see vol. ii. p. 322); and that, when he speaks of the connection of the diseased mass with the vessels of the skull; its connection by the bone; and its extension under as well as above the cranium. Here I think Walther is as strong in saying that mass of these things necessarily be reduced, as others would be in assuming that it is the contrary manner to be reduction. These reflections must chiefly depend upon the size of the swelling, in relation to that in the aperture in the skull.

Generally speaking, fungus haemorrhoides of the dura mater are very dangerous, as well on account of their nature as of the difficulty of curing them in any certain manner, and of the danger and external disease which they very frequently. Such as have a pedicle, the base of which is far extensive, which are now in those positions, or than much diseased in the surrounding bone, are, nevertheless, not very painful, and in persons who are in rather remote parts, and are in general regarded to be the least serious. These are the cases in which a cure may be attempted with a hope of success, though the operation is almost universally doubtful.

When the seat of the disease has been just pointed out, when the disease is of long continuance, and the brain already affected, nothing dangerous can be expected.

Craniotomy is the most simple means of cure, and

one which has manifestly succeeded in such practitioners as have mistaken the disease for an aneurism, or a fungus ossifer. The efficacy of this method has been further manifested, because the tumour when not very large, has sometimes been partly, or even wholly, reduced, without any bad consequence. This has no little shown in looking to expose accurately the true character of the disease, that, as might be imagined, the reduction only being attended with temporary success, and having no effect whatever on the original extent of the disease, the symptoms returned, and tumours were again the nature of the aneurism was discovered. There is a fact in the memoir of M. Louis, which tends to evince that good effects may sometimes be produced by compression judiciously employed. A woman brought to the birth, of the growth by symptoms attended by a tumour of the sternum, having remained with her head for some time in the same way as the tumour, found the swelling so suddenly reduced, without any ill effects, that she thought herself cured by some means. Compression, artificially kept up by means of a piece of tin bound to her body, prevented the pulsation of the tumour again. The pressure, however, not having been always very strict, the erysipelas very soon and then returned, while the tumour was in the act of being depressed again, and then afterwards cured, on the swelling having assumed a solid pressure. The symptoms were therefore occasioned by the irritation which the tumour suffered, in passing the incision against the opening through which it protruded. The patient lived in this state nine days, having every now and then fits of insensibility, in one of which, attended with hicough and vomiting, she expired.

As long pressure cannot be depended upon, the following method may be tried. In cutting through the cranium with a knife, which is certainly preferable to sawing, the action of which is very tedious and painful, and can never be limited or attended with any degree of precision. A circular incision may be made through the scalp covering the tumour, and the flap dissected up, and reflected as in solving all the best circumstances like view. Then with trepan, repeatedly applied, or with wire would be better, Mr. Hey's saw, all the toughs of the bone should be carefully removed. Now, if it be true, that the vessels of the skull are chiefly concerned in the supply of the diseased mass, we see that the source of its growth must be destroyed by the foregoing proceeding.

The tumour, thus disengaged on all sides, may be cut off with a scalpel; and such arteries as third much should be tied. Then instead of applying caustics, as sometimes advised, perhaps it would be better to remove every part of both layers of the dura mater immediately under the situation of the aneurism. By this means, and the removal of the surrounding bone and tissue, all chance of the regeneration of the tumour would be prevented. In ascertaining the existence of a fungus of the dura mater, it is certainly an interesting point to know whether the tumour has an intimate vascular connection with the dural and pericranium, as asserted by Walther, and some other respectable authorities; though the importance of the information on this subject to the practitioner is seemingly lessened by his being aware that it is necessary always to begin with moving away the bone in the immediate vicinity of the diseased mass. In the *Journal* of 1810, vol. ii. Walther found the pericranium thickened by a considerable extent around the disease, and closely connected with the tumour by vessels. — (Ibid. vol. ii. p. 164.)

When the disease is aneurismal, and its pulse small and narrow, no mistake happens, we should not hesitate to cut it off.

This method is admirable in trying the case with a scalpel; a plan which could not be executed without dragging, and seriously injuring the dura mater; and the fatal effects of which I saw exemplified in the case of a young man, years ago in St. Bartholomew's Hospital, and was repeated upon in the late Mr. Jameson. However, it is also preferable to remove, when cause great pain, but very often contraindicated. In preparing the extraplanum, we should remove no whole extent of the cranium, and, if possible, be run, even though it may extend as deeply as the diseased part of the dura mater. This step must not be delayed, for the danger will continue to increase as we go on to effect the cure, become incurable, and even mortal. It is likewise

decides that we must impute the income which attended the treatment of the Standard Ackerly, of whom *Melania Austriaca* develops another instance. The same income was attended with inadmissible inequalities, which no remedy could affect. It was proposed to him to form the standard, in operations to which he consented. This proceeding brought into view, under the name, a *Phryganea* *paucicornis*, the destruction of which proved a permanent cure of the violent pains which the stomach had sustained. It is not mentioned in the case whether the inferior layer of the daily excreta was healthy or not, but there is foundation for believing that it is the excretion of these materials be overlooked in time, and foul residues be pursued, as to the instance past cited, success would often be sought. Indeed, reason would suggest this means; in fact the disease is not endemic, it is necessary to expose a small number, some of the daily matter.

It appears to me, however, that trespassing can never be warranted, unless the owner can be indicated by some external change. I saw my late master, Mr. Hadden, trespass first for a more lined path in one part of the land, on the suggestion that there was a stream under the tree, but no stream was found, and the cottage which reflected on the dark tunnel, and moved first.

No doubt, in some cases, the insurance will be considered, at least overlaid in the instance in which

Williter made an incision on the base of one of these fungi, in order to ascertain its nature: two pairs of blood vessels (one from several vessels of very large size) were thereby secured, and the further use of the knife discontinued.

M. Léniz has described many tumours which grow from the surface of the dura mater, while that membrane has been found, as after the application of the bistoury. They only seem to differ from the prolatas in not existing before the opening was made in the skull. Tumours of the dura mater should not be confounded with meningeal cysts. (See this article.) See, on the preceding subject, *Mém. sur les Tumeurs fontinales de la Dure-Mère*, par M. Léniz, in *Ann. de Chim. et de Méd.*, 1786, *Encyclopédie Méthodique*, *juris*, *Chir. art.*, *Dure-Mère*. J. N. Macbarnet, de *Tumours Capitis fungosae* and *Cervicis Cervicis cystis*. *Reprint*, 1712. *Journal, Pathologique*, t. 1, p. 467, &c. 1800. J. and G. Whistler, über die Schichten des Arachnoidei der menschlichen Hirnhaut. *Phil. Magaz.* 1811. In this work, the observations of M. Léniz are explained. PK = 1846 in *Journal für Chir.*, von C. Graef, &c. t. 1, p. 55, &c. 1850. Berlin, 1850. The latter brings 215 cases from the quarters of the Wundtoll, and of various figures contributed by from Léniz on several points, some of which I have noticed, as the foregoing facts.

AN again so valuable and necessary to the perfection of our education as the ear itself have all the symptoms of surgery wanted for the preservation of its integrity, and the removal of the diseases with which it may be affected. What, indeed, would have been our lot, if nature had been less liberal, and not infused into us the sense of hearing? As Leibnitz has observed, we should then have been as mutilated for the want of instruction, a principal part of divine and human knowledge would have been closed; and, there being no improved communication of ideas, our little reason could never have approached perfection. Even our life itself, being as it were dependent upon all such bodies as surround us, would have been immediately exposed to surgery. The eyeight serves to render us conscious of objects which present themselves before us, and when the judge there to be harmful, we endeavor to avoid them. But to say nothing of our liability of being injured all sides at once, our eyes become of no service to us whenever they happen to be enveloped in darkness. The hearing is then the only sense that teaches us our safety. It warns us not only of every thing which is moving about us, but likewise of every thing which is moving about us, but likewise of every thing which is moving about us. Each are the inestimable advantages which we derive from that organ. Its importance when healthy places it nearly at the utmost efforts of surgery when diseased.—(See Sermon in *Memoirs for the Society promoting pure & free Protestantism*, by the Rev. John G. Campbell, D.D., 1793, p. 121, 122, of 128th.)

It is not in my Youth, even the diseases of the age were so seldom as might the greatest physicians and the most cautious opinions presented; and indeed how could any correct pathological information be expected from a student who had not given a complete and accurate description of the signs itself? Also, notwithstanding what has been here said respecting the studies of the ear, it is generally admitted that poor and equally deficient examinations and reserved history. Though Erasmus, Valerius, Vergara, &c. expelled some of the diseases which crossed this branch of surgery, they left a gross and obscure. Since their time, science has been enriched with the valuable discoveries of Celsus, Mercur, Scarpa and Casperini; the first two of whom demonstrated that the tympanum is filled with a liquid fluid, and not (as was previously held) with gaseous air; while the last two distinguished anatomists directed the guide with new and very valuable descriptions of all parts composing the labyrinth, especially the semicircular canals.

In 1762, the French Academy of Surgery agreed to

[illegible]

that investigating the tactile sensations of so many sorts of emotions, the pathology of the internal ear, and the treatment of its diseases, are far, I may say, very far, from a high state of improvement. To further advance indeed were discouraging obstacles pointed themselves; the auditory apparatus is extremely complicated; the most important parts of it are hidden out of the reach of ocular inspection; the anatomy of the organ is perhaps not yet completely unveiled; the exact uses and action of several parts of it, especially the ear, are still involved in mystery; (the appearance of discharging the ear is a state of disease all too common frequently curable without it; and even when they are needed, and when vestiges of themselves are perceived, are traced in extraneous parts of the organ, the utmost is finally experienced in drawing any useful practical conclusion, because the natural uses of those parts, and the precise manner in which they contribute to the perfection of the ear, are not known to the most enlightened physiologists. We are very sorry to be able to point out to them as a weakness would be to use it, in examining the interior of a watch, to find some broken, and out of order, the exact state of which is the perfection of the instrument, we feel not first studied and comprehended. As last, the physiology of the ear is but very imperfectly understood; and, as Broussais remarks (*Ann. Chim. Phys.* t. 6, p. 17), it notwithstanding the progress made in optics, and the complete knowledge of the structure of the eye, a perfect explanation has not yet been given of the phenomena of this organ as an instrument of vision, no farther was that, with far more circumstantial information

The epidemics, and on removing it the next day several small round worms were observed upon it, and from that period all the symptoms disappeared. To this cure we shall all ascribe from Marignac. A young woman, somewhat fatigued, and tired long that when she was a girl a worm had been discharged from her left ear, that another one about six weeks ago had also been discharged very much like a small silicious vesicle. This event took place after every attack pain in the same ear, the forehead, and temples. She added, that since this she had been tormented with the same pain at the frequent intervals, and so severely that she often swooned away for two hours together. On removing the discharge, a small worm was discharged, of the same shape, but much smaller than the preceding one, and she was now afflicted with deafness and headachings on the forehead. After leaving the young Valentin no longer entertained any doubt of the verminous state of the tympanum being destroyed. He proposed the employment of an everted intubation in history such worms as so mentioned. For this purpose distilled water of St. John's wort, in which mercury had been agitated, was used. In order to prevent a protrusion of the tympanum, Marignac recommended the affected ear to be closed up when the patient goes to sleep, is restless and painful. If this be soon done, this, attracted by the application, will the worms withdraw, and while the patient is unconscious deposits their eggs in the ear. After, in speaking of worms generated in the middle ear, however, that there is no better remedy for them than the discharge of yellow matter, as reported on the ear several times a day. However, as this plan cannot always be pursued, as refusal or refusal to be of service may be tried, a few drops of whiskey to be introduced into the ear and retained there by means of a cotton ball of cotton. This method, which is not injurious to the lining of the passage, is fatal to worms, and especially to moths. When caterpillars, ants, earwigs, and other insects, have introduced themselves into the middle ear, they may be treated with a piece of fat smeared with honey; and when they cannot be dislodged by this simple means, they may sometimes be killed with a small piece of paper. In general, however, charred wool and expedient practice for the removal of small insects, such, beetles, and other earwigs, better than the middle ear, as to throw cold water into the passage with a proper syringe, by which insects they are forced out with the fluid. When the loud or violent vibration is usual, according to Mr. Richardson, the best mode of extraction will be by means of a syringe and injection of tepid water. For this purpose the palm of the syringe ought to be pressed gently against the side of the ear, so that it may occupy a little of the diameter of the tube as possible, and when the injection arrives at the eardrum tympanum, the respiration will force the head or other substance outward. It is to be rather large, if any perhaps remain at the entrance of the ear, where it ought to be extracted by means of a pair of forceps. [See Richardson's Illustrations of Acoustic Surgery, p. 43.]

A *White Savage* (May, 1928) was called in, a child about two years and a half old, who seemed whose case a publicist, and even the other a French being, had been placed in another child, and requested there for an interview, making complete delusion and extreme suffering. It then occurred never far from the car, I was followed by these things, which by close against the [presumably, entirely hidden by the wooden seats of the back of the car, and it was not, and, and] discharges. With a last point (the extractions were this really effort). Several enormous, perfectly spherical, and found in their catheters to remove the substances in other methods.

The business of buying horses is the pre-arranged scene, the most characteristically complete, as we may see in the fourth advertisement of *Polaris* (Hildenes, Cor. 12). After first surveying, we find both successively presented, and in this event all their industry produces a full of glass from the left ear of a Native girl, the picture itself herself abandoned to the most magnificent pose, with her extended to all the side of the boat, and bent, after a considerable time, was followed by a passage of the left side, a dry course, suggestion of the moment, multiple movements, and a better symmetry of the left arm. Hildenes comes

her by extracting the piece of glass which had remained eight years in her ear, and had been the cause of all this trouble. Although the extraction was never been very difficult, it does not appear that Hildanus found it necessary to practice an incision before the act, as some authors have advised, and among them Keesley, who has quoted the foregoing case. We have agreed with Lindesmith that such an incision does not seem likely to improve the effect very materially; for it must be on the inside of the external osseous capsule, which is in the largest part of the canal. The incision strikes us as an unnecessary violation of the integrity of the passage, for Keesley has observed that it is not such obliquity of the osseous canal as forms the basal thickness as a great impediment; for as it is flexible it may easily be made straight by moving the external os upwards. Hence Fothergill, of Acadia, pointed this specimen first prepared by Falcas Agneta, and it is very discoloured by Dr Lindesmith.—(Paris de l'École de Médecine, t. 9, p. 112, 113, 114.)

Wallerian relates a case in which a small ball, which had been pushed into the external auditory meatus, was by operation into the cavity of the tympanum, where it thence formed, which corresponded with the situation of the cranium.—*Ann. des Sciences Méd.* 1.7, p. 51.

B. *Statistical Analysis: Restricted with Rational or Random Detectors*

[illegible]

The hydrogenated lipid, proteins of wax, if neglected, may ultimately produce absorption of the glycerium and other various tracheae. Thus, in any case, Hane and Chavasse found the heads of the nucleus separated from its level, partly destroyed and covered with the hardened carbon that had made its way into the Glycerium. (See *Dev. Arch.*, 1902, p. 20.)

*The symptoms (says Mr. Marshall) which are attributed to the imagination of the ovaries are pretty well known. The patient broods, has inability to bear, complaints of nausea, particularly at night or confined to bed in menstruation, and of heavy sexual life, the nervousness, stoniness of a laborer.

The quadrilateral is also the subject of such symptoms in support the existence of war; but the way remains a little different by explanation.

Any means capable of removing the imprisoned man may be adopted and attaching the man's wrists with warm wax or in the past, spindly and effeminate, and the only means necessary. At the same time, the (a)gent is immediately removed. — (Amory of the human fair, with a Preface to its History, by J. C. Smith, n.d., p. 72, 73.)

In order to remove its impurities from the car by its effort, a sponge capable of holding dirt and oil in its pores, should be employed; and the kind is joined with a good sort of sugar, care being taken to let it water in the natural direction, and not against one of the sides of the pithway. The sponge must also serve merely to wipe thoroughly into the car, as is taken the hygienic. As the final regulations with considerable regard, a small basin is to be held close up to the ear at the time of using the sponge, so as to catch the water and hinder it from wetting the patient's clothes. The food water prevented in this way, a turpentine is also to be fed over the shoulder. In general, it is necessary to direct

was restored, though it was lost again when the wound closed. Hence a new opening was made, and kept from healing by means of a piece of gutta. The patient was afterwards able to hear when the mouth was open.

The perforation of the tympanic process was not approved of by Morgagni; indeed, it never often fails, as both Magagnoli and Hagström have observed, on account of complete bony partitions preventing all communication between the middle cells; and sometimes the tympanic process, instead of being cellular, is perfectly solid: an instance of which is recorded by A. Murray.

14. Direction of the Labyrinth.

There are much more diversified than might at first be supposed, and if we select the two principal cases, and to depend upon the state of the bony of the ossicles, there are not less than seven different species of dislocation affecting the labyrinth. 1. Dislocation of the tympanic oval and fenestra towards, or upwards, backwards, &c. 2. Malposition of these apertures. 3. Malposition of the labyrinth. 4. Inversion of the cochlea in relation with the vestibule. 5. Alteration of the base of the cochlea. 6. Deficiency of the same fold. 7. Adhesion of the nerve of hearing.

No doubt disorders (and that kind of it which is frequently called the most difficult test) often arise from an amenable state of the periotic molles of the auditory nerve, or of the structure on which its filaments are spread. This affords an analogy to the dislocation of parts within, in which, though every part of the eye may seem to possess its natural structure, sight is lost, because the part is light only strikes against a paralytic or immovable retina. Mr. Saunders has noted this view of two deaf patients with the greatest care, but never discovered the least deviation from the natural structure. In the commencement of deafness from a paralytic affection of the auditory nerve, Mr. A. Cooper remarked, that the sensation of resonance was diminished, and when the deafness became deeper, was totally suppressed. And another particular symptom of paralysis of the auditory nerve, pointed out by the same author, is the patient's inability to hear the sound of a watch placed between the bony teeth.

With respect to the causes of a paralytic affection of the auditory nerve, they are mostly based in great debility, and some of these probably depend upon congenital imperfection of the nerve or brain itself. It seems, however, that a part of the causes to which we allude are mechanically, as an extrusion of blood, a distension, or an exposure; while others operate on the ear by sympathy, as in the case when deafness is produced by the presence of worms in the bowels.

Mr. Saunders remarks, that all the diseases of the internal ear may be denominated nervous deafness; the term, in this sense, embracing every disease, the result of which is in the nerve, or parts containing the nerve. Nervous deafness is attended with various conditions in different cases, some in the head or sensory kind, the occurrence of water, the hearing of a hoarse little, rattling of bones, howling of wind, &c. Other persons speak of a hearing noise, corresponding with the pulse, and increased by bodily exertion, in the same degree as the action of the heart.—(Saunders, p. 31.)

According to this author, there is a specific species of nervous deafness, attended with a sensation of some of the above-mentioned causes, and was once cured, in which the hearing was completely restored in three weeks, by a mercurial course.

Mr. Saunders observed several cases of nervous deafness, by restoring patients to low diet, giving them calomel freely, repeated doses of sulphate of soda, mustard, sometimes frictions, sometimes blisters, or, according to circumstances, and applying blisters behind the ears, at intervals of a week. The plan requires permanent use.

Electricity has been highly recommended for the cure of nervous deafness, though the prospect of benefit from it seems entirely depend upon the nature of the cause of the infirmity. It is observed to be sometimes useful in cases of locomotor paralysis of the auditory nerve; but it cannot be of any service where the Electricity takes the activity of the tympanum, or the muscular cells are contracted. It is less down as hearing, when the patients are very debilitated and subject to

vertigo, arising from the noise, great interference of blood to the head, &c.—(Edinb. and Sciences Med. t. 26, p. 124.) The evidence in favour of the efficacy of galvanism is still highly scanty and unsatisfactory.

Whether in certain cases of deafness from action of the auditory nerve the introduction of some injections into the cavity of the tympanum, through the Eustachian tube, will answer to the remedy used by a late writer, forms a question most debatable.—(Edinb. and Sciences Med. t. 26, p. 120, 122.) The effect of the nature of the matter, in some of these cases, may also merit further trial.

This article, I think, may be usefully concluded with a few general but sensible observations on the various kinds of deafness, made by a modern writer. According to Professor Rosenbach, all the disorders of the sense of hearing may be considered under three principal forms.

1. Deafness (Stetitio, Cytisus), in which the faculty of hearing associated sounds is completely abolished.

2. Hardness of hearing (Dysacusis), in which the faculty is so diminished, that several distinct sounds cannot be heard, without the assistance of a particular apparatus.

3. Alteration, or distortion of hearing (Paracusis), in which the faculty of hearing associated sounds in the natural way is imperfect for want of precision.

1. Deafness. Rosenbach distinguishes into four degrees, the first of which is marked by an absolute impossibility of hearing at all; the second, by a power of still distinguishing certain sounds, as murmuring, the voice, &c. The first is usually congenital, and a cause of idiocy.

The discrimination of these four degrees. Rosenbach considers of great importance, especially in relation to the deaf and dumb; because the pathology and cause of each with which these persons are sometimes gifted, is apt to be mistaken in the faculty of hearing. This fact is illustrated by some interesting experiments made by Flourens on deaf and dumb persons. (Voyage de Flourens aux Indes, t. 2, p. 32.) A deaf and dumb girl, who was a needlework in a work near the house-door, regularly gave notice whenever it was opened or shut. As the door was furnished with a little bell, which rang loud enough whenever the door moved to be plainly heard in the neighbouring room, and with the exception of this noise, no other noise or sound could be distinguished, Flourens was surprised at the circumstances. Numerous observations have the girl really knew about the movements of the door, he asked the bell to be rung with great force without the door being opened; the bell was perfectly unconscious of the noise. The bell was afterwards kept still, while a person entered and shut the door so softly, that Flourens himself could not hear it; yet the child instantly gave warning that somebody had entered. The inference was, that the child, on which she was conversed to her legs and back, certainly listened, which made her conscious of the motion of the door.

The discussion of the state of deaf and dumb persons has excited some false explanatory of the nature of the loss of hearing. Among other things, it appears, that complete deafness, whether congenital or acquired, more frequently depends upon normal alterations of the soft parts, than upon any interference in the formation of the bones. Thus, in the head of a person who had both deaf and dumb while living, Flourens found the auditory nerve diseased in size, while every other part of the organ was perfectly normal. Anatomists found the nerve harder than common. Dr. Hufschmidt, with an instance, in which the vestibulum was filled with a viscous substance.—(A case of internal deafness, in Mem. of the Med. Society, vol. 3, p. 4-15.) Dr. Murray and Marshall found the auditory nerve severely compressed by a shrinking. In some cases, I have found even part of the ear apparently so altered, that the deafness could not be ascribed to paralysis of the nerve. In others, the infinitely dependent upon, structure of the cochlea. In a third, the cavity of the tympanum and the vestibulum contained small portions of calcareous matter. He has also seen the tympanum filled with a thick, yellow lymph, or a thin fluid encased in calcareous cells. In the dissection of the head of a deaf and dumb person, Rosenbach noticed,

among other remarkable circumstances, a greater hardness of the auditory than of the facial nerve, and preternatural firmness of the malleus obliquus; thickening of the membrane of the tympanum, the bony roof of the cavity of the tympanum not thicker than paper; and just over the junction of the malleus with the incus the bony substance was so absorbed, that an appearance like that of membranous tissue resulted. The round cells, many of the tympanum, and the Eustachian tubes, contained a limpid yellow fluid. In the tympanum, the peritremum was thickened, forming small discoloured tubercles, which were of their natural structure. Nothing particular was remarked in the labyrinth.

In a small proportion of instances, the above degree of deafness has been traced to anomaly in the structure of the solid parts. Thus, Monro found the cochlea composed of only one stria and a half—(Op. cit. Acad. Regiae, 1791, t. 7, p. 422.) Valentin found the stapes adherent to the fenestra ovalis (De Aure Mammalia, cap. 11); and Reissner notices a case in which the ossicles were entirely missing—(Mémorial de l'Acad. de Turin, p. 57.)

In the first degree of deafness above described, which, when verified, must excite suspicion of serious inflammation of the organ and abolition of the nervous influence; and when stopped, indicates a complete cure of the function of the nerve, the prognosis is favourable. However, it must be recollected, that the degree of the disease, though only a partial imperfection of the organ and nerve can be supposed. On the other hand, when the latter degree is acquired, there is more prospect of relief, because merely a partial alteration in the solid parts is to be supposed.

2. *Hardness of hearing.* Broussais also distinguishes several degrees of what is termed hardness of hearing. In the first, the patient cannot hear a clear voice, and especially high tones, but can perceive, though it is true, not with very distinct notice, articulated sounds, when the voice is a good deal raised. In the second degree, he hears and distinguishes both high and low tones very well, and also words, but only when the voice is somewhat raised.

These two cases are better understood, inasmuch as it is tolerably well ascertained that the immediate cause of the deafness is some alteration in that part of the organ which serves as a conductor for the vibrations of sound, or else an increased sensibility of the nerve of the internal ear being in other respects right.

Among alterations of the conducting parts of the organ, Broussais distinguishes:

1. A total obliteration of the tympanic membrane, or, at least, its perforation, or complete absence. These cases have almost always been attended by a suppurative inflammation, the patient only hearing when some solid bodies are placed between the eardrum and the bull peritremum of sounds does not appear to be much lessened when the ear is perforated.

2. Diseases of the cavity of the tympanum, as—obstruction of its parietal membrane, thickening of its parietes, or collection of blood, pus, or other fluid, in its cavity. Broussais thinks there can be no doubt that inflammation and suppuration in the tympanum are much more frequent than is generally supposed; the former affection being often resolved by a slight access of inflammation. In describing aged subjects, he has frequently noted the appearance of the tympanum thickened and opaque, and he could only impute this appearance to previous inflammation.

After detailing a few structures of the system of perforation within the tympanum, and a few observations on noise and vertigo as they in themselves carry Broussais into the hardness of hearing, considered with nervous erasibility, is the treatment of which, even, he admits upon the advantage that would result from a knowledge of the particular species of morbid alteration prevailing in the patient. But as nothing very certain can be made out of this point, and still less can we know their directions of force, than the different causes either in a combination of them, or in the part, or in a partial paralysis of the auditory nerve, the exact nature and time of which are quite unascertainable, this absolutely necessary to which, only in the progress of the disease, attention is paid. This disease will be far different, but, if the patient has been previously very sensible to the sound of the voice, or sound in general; when

if the power of hearing has been lost all at once, and without any mark of inflammation; &c. If the affection coincides with other nervous diseases.

3. *Alteration in Direction of Hearing.* Between the most perfect hearing, congenital or acquired, and this point of disturbance of the faculty of hearing, Broussais observes there are a great many degrees, the cause of which is the most difficult to comprehend, as the constitution of structure, which enables every part to perform its functions with freedom and precision, are not yet made out. If, even so, it were in our power to determine what is truly the regular structure of each part, we should then be furnished with a means of judging correctly of the anomalies of function, the changes in which would be indicated, gave efficacy as in the eye, by studies of organization, similarly in the same way as we judge of the modifications which the trunk of vessels must undergo at the bottom of the ocular artery, by the diameter of the vessels of the common or less, or the constancy of the other innervation.

In the present state of physiological and pathological knowledge of the ear, therefore, Broussais observes that little can be attempted with regard to a scientific classification of these cases of altered or disturbed hearing. As the cavity of the tympanum makes constant use of the parts which have principal influence over the vibratory motion, and in that share is the propagation of vibrations and sounds, their faulty condition must be chiefly the subject for consideration. And under their numerous defects, traced by observation, and already specified in the foregoing columns, Broussais particularly calls the attention of the reader.

1. To alterations of the membrane of the tympanum, whether proceeding from congenital malformation, or disease, or from thickening, contraction, perforation, or inversion of the same part.

2. To the induration of some part in the cavity of the tympanum, more frequently produced than is commonly supposed by obstruction of the Eustachian tube. In most new-born infants, Broussais has also found the cavity of the tympanum filled with a thick, elastic gelatinous fluid, which for some days is non-absorbed, and is probably the cause of the indurative excited by new-born children to sounds, which are even as it seems as to be offensive to the ears of an adult.

3. Alterations of the membrane of the fenestra ovalis, such as its imperfect formation, or erroneous situation, its thickened state, &c.

But it is remarked by Broussais, that as the difference in the intensity of sound may occasion a modification in the sensation of the ear, the merely conducting parts of the auditory apparatus need not be forgotten, as the external ear and the ossicles influence extension, which regulate the quantity of sonorous waves striking the auditory nerve. However, the transformations of the ossicles and the state of the eardrum, some secretion within it, are observed by Krüger and Lentin (Ueber das Gehör, Göttingen, 1799, 8vo, 1799) to have more effect on the hearing than defects of the middle itself, the whole of which, as we have stated, may be lost without any material deafness being produced. Lastly, Broussais calls our attention to the nervous action or influence, which, whether too great, or too small, may equally render the hearing dull; and some useful observations on the case just now by Broussais, from attending to the patient's sensibility—(see Broussais, *Opuscules*, t. 5, p. 224, &c. *Journal de Médecine*, 1800, t. 10, p. 100; *Journal de Médecine*, 1801, t. 11, p. 100; *Journal de Médecine*, 1802, t. 12, p. 100; *Journal de Médecine*, 1803, t. 13, p. 100; *Journal de Médecine*, 1804, t. 14, p. 100; *Journal de Médecine*, 1805, t. 15, p. 100; The causes of erythema are falls, blows, sprains, etc., which occasion a rupture of the blood vessels on the surface of the body, and a subsequent effusion of blood, even without any external break of continuity. Erythema is one of the symptoms of a contusion.—(See Contusion.) A considerable erythema may be caused from a very slight bruise, when the ruptured vessels are capable of pouring out a large quantity of blood, and particularly when the parts contain an abundance of loose cellular substance. In general, erythema does not make its appearance immediately after the blow or sprain, but sometimes waits several hours after the application of the violence; at least, it is not till this time that the local, blue, and livid colors of the skin is most conspicuous. A thick vein, which is only an erythema, is always soon discolored six or eight hours after the receipt of the blow.

In the article *Bleeding*, we have noticed how an epistemic *why* can arise from the focal getting out of the way (in the adjacent cell) of the sentence.

Common uses of emulsions may generally be easily cited by applying the standard formula, and an emulsifying base of itself does not add particular risk. The most typical applications are emulsions of the water-soluble emulsifying agent, run through, and the liquid emulsion, such as:

The object is to meet this aim, and to provide the atmosphere of the experimental field.

In cases of occupations, I have seen such persons lead the practice of increasing collections of extraneous food by means of almsgiving, that the plan of examining it by an analyzer seems to me to be unnecessary. When an animal is made and as is obtained the portion of blood which cannot be prepared in upon parasites, and extensive infestation and suppuration are the frequent consequences.

The quick and powerful action of the absorbent results in rapid extrusion of blood, one pulse in 10 seconds, and in 10 minutes the patient is no longer called in question, when we find no record in medical journals, that the largest hemorrhages are thus speedily dissipated and removed, after the operation of tying the arteries, from which each hemorrhage arises.

[illegible]

ENTRUSTMENT. (From *Entrust*, to trust.) A casting out or an revulsion of the eyes.

According to reports, there are two species of this genus, one provided by an American wildlife official and a young of the species which not only makes their appearance in the market, but also breeds them in the country (see report). The other species from

2. retraction of the skin of the eyelid, as in weeping, by which the edge of the eyelid is first rendered far more dense than the eye, and afterward turned respectively out, together with the whole of the affected eye.

The marked swelling of the lining of the azygos, which causes the first species of tetraplegia (gelling out of joints) consideration of a similar infection (endocarditis) and not, arises mostly from a congenital lack of the venous, afterward increased by chronic chronic endocarditis, particularly that of a valvular nature, or mixed, endocarditis, or else the disease originates from the small-pox, affecting the eyes.

While the disease is confined to the lower eyelid, as it most commonly is, the lining of this part may be observed rising in the form of a semicircular fold, of pale red colour, like the tarsal granulations of psoriasis, and intervening between the eye and eyelid, which hinders it in some measure from closing. When this swelling is accompanied by the rising of both the eyelids, the disease assumes an angular shape, in the centre of which the eyelid seems sunk, while the circumference of the ring swells and crums the edges of the two eyelids so as to cause both great irritation and deformity. In each of the above cases, on pressing the sides of the eyelids with the point of the finger, it becomes manifest that they are very capable of being elongated, and would readily yield, so as strictly to cover the eyeball, were they not prevented by the interesting swelling of their membranous case.

Besides the very considerable deformity which the above produces, it causes a permanent dimming of both the eye and the skin, and, when it occurs, a distension of the epinephal, frequent spontaneous attacks of chronic catarrhal, incessant itching of the skin, and, finally, opacity and immobility of the cornea.

[illegible]

Although in both species of ectoparasite the lining of the abdomen is usually sensitive, yet the response is usually stronger in *Ichneumon* than in *Phaenocarpa*. For in the first the skin of the eyelets and adjoining parts is not disturbed, with acids, and by pressing the external eyelid with the point of the finger, the lid trembles with ease over the eye, where it is not so for the latter species, although sensitive. But in the second species information, besides the above-said, consists also of contraction of the skin of the eyelets or adjacent parts, because often it needs to cover the eye with a muscular fold, by pressing upon the latter part with the point of the finger, it does not give way, so as completely to cover the globe, or only yields, in a slight way, for in this manner, as it does not move in the least from its normal position, by means of the information of this kind, having been so accurately destroyed that their eyes can become adherent to the ends of the antennae.

Mr. Graham expressed a plan to present an

apical inflammation, accompanied with contraction of the integuments of the eyelid, but without any marked disfigurement. It is described by him as usually taking place after a long continuance of lachrymation, and proceeding from the contraction, contraction, and thickening of the skin, "the result of the passage of the vitreous secretion over it, and which, by dragging on it, causes the irritation."—(In the *Operative Surgery of the Eye*, p. 50-55.) This form of the disease, according to Mr. Gifford, is rarely attended with such a thickening of the lower lid as requires it to be removed with the knife or scissors; for it subsides with the removal of the complaint.—(P. 66.)

According to Scarpa, the cure of ectropion cannot be accomplished with equal perfection in both its forms, the second species being, in some cases, absolutely incurable. For, as in the first species of ectropion the disease only depends upon a partial thickening of the internal membrane of the eyelid, and the treatment mainly consists in removing the redundant portion, art possibly may effect a cure of it. In the second species, the chief cause of which arises from the loss of a portion of the skin of the eyelid or adjacent parts, which loss is known either to be congenital, or acquired, and is not capable of effecting a perfect cure of the disease. The treatment is confined to removing, as much as possible, such complaint as results from this kind of exposure, and this may be done either by means of astringent treatment, according to the loss of skin of the eyelid in the first grade. Cases in which no such skin is deficient, that the edge of the eyelid is adherent to the margin of the orbit, Scarpa considers as incurable. Now for the reasons he reaches, he thinks, that always to be estimated by reasoning to what point the eyelid admits of being retracted, or being gently pushed with the end of the finger towards the globe of the eye, both before and after the employment of such means as are calculated to effect an adhesion of the skin of the eyelid, for it is into this point, and no further, that art can reduce the eyelid, and consequently keep it in place.

When the first species of ectropion is recent, the finger's swelling of the lining of the eyelid not considerable, and consequently the edge of the eyelid not much turned out, and in young subjects (for in old ones the eyelids are so flaccid, that the disease is incurable), Scarpa prescribes desloughing the flaccid surface of the internal membrane of the eyelid by the repeated application of the astringent mixture. Mr. Gifford teaches the flaccid portion of the conjunctiva every four days with a probe dipped in sulphuric acid, and gently applied every day, or every second day, the salivary of copper, at the same time yet creating some transverse incisions, which he also employs to cause pressure from contraction of the skin independent of any astringent, and which I shall presently notice.—(On the *Operative Surgery of the Eye*, p. 75.) In recent cases, where the patient is weak and irritable (or a child), Scarpa recommends the treatment with simply applying every day the liniment of opium, which often a time is to be strengthened by the addition of opium. To the relaxed conjunctiva he afterwards applies exclusive eyelashes, and last of all the use of silver and nitrate of mercury. When the part is hard and relaxed, the employment of cauter is preceded by scarification.—(Letter, &c. 2, p. 136.)

For removing the considerable and immoderate size of the first species of the disease, Scarpa and Gifford are agreeable for cutting away the whole or the flaccid swelling closely from the vascular membrane, on the inside of the eyelid. The following is Scarpa's description of the operation.

The patient being seated with his head inclined backwards, the surgeon, with the index and middle finger of his left hand, is to keep the eyelid steadily fixed, and holding a small pair of scissors with the convex edges in his right, he is to cut off the whole redundancy of the internal membrane of the eyelid as near to the base as he can. The same operation is then to be repeated on the other eyelid, should that be affected with the same disorder. If the excision be effected with a sharp edge that is curved to exactly imitate when the operation is made be raised as much as possible with Scarpa, or a double-pointed hook, and dissected off at its base, by means of a small bistoury with a convex edge. This last mode is preferred by Scarpa to the use of scissors, and I confirm that it has always

appeared to me the most convenient. The bleeding, which occurs at the beginning of the operation as if it would be copious, stops of itself, or as soon as the eye is bathed with cold water. The surgeon is then to apply the dressings, which are to consist of two small compresses, one put on the upper, the other on the lower arch of the orbit, and over these the sitting liniment, in the form of the emulsion, or an ointment as it compresses and replaces the edges of the eyelid, in order to make them meet the eye. On the first removal of the dressings, which should take place about twenty-four or thirty hours after the operation, the surgeon will find the whole, or almost the whole, of the eyelid in its natural position. The treatment should afterwards consist in washing the skin of the inside of the eyelid twice a day with warm water, or barley water, and contact, rest, until it is completely well. If towards the end of the cure the vascular action assumes a dangerous appearance, or the edge of the eyelid seems to be too distant from the eyeball, the wound on the inside of the eyelid must be re-cut several times with the appropriate instrument, for the purpose of destroying a little more of the membrane lining, so that when the inflammation subsides, a greater contraction of it may take place, and the edge of the eyelid be drawn still nearer to the eye. Proper steps must be taken, however, for restoring the principal cause, in which the ectropion depends, particularly chronic ophthalmia, a relaxed and morbid state of the conjunctiva, &c.—(See *Op. Oculi*.)

In England the extension of the flaccid eyelid portion of the conjunctiva, in cases of ectropion, has been very much misapprehended for the employment of cauter. The difficulty and almost total ineffectuality of dissecting off every particle of the flaccid membrane under the practice of cauter is much less certain than the treatment with cauter. Thus we see that Scarpa, who is not an occasional failure, and the necessity of his having recourse to the operation. He does not allow the employment of cauter to follow the use of the latter.—(Alat. des Yeux, p. 165.) In the ectropion, from a relaxed flaccid state of the conjunctiva, the employment of permanent ophthalmia, the Voss's ligature with a light careful application of the astringent mixture to the whole granulated surface. The eyelid part is then to be returned, and secured in its place with a compress, and straps of plaster as a bandage. When the eye is closed, the same things are to be kept up, and in the course of a few days the tendency to protrude will disappear.—(On Diseases of the Eye, p. 168.)

In the second species of ectropion, or that produced by an accidental contraction of the skin of the eyelid, or neighbouring parts, Scarpa observes, that if a contraction of the conjunctiva has proved capable of turning the eyelid, the removal of a piece of the internal membrane of the part, and the cicatrix which will follow, will also be capable, for the same reason, of bringing back the eyelid into its natural position. The same nothing can remove the thick skin, the shortened end of the whole eyelid, in whatever degree it comes, must always continue, even after any operation the most judiciously executed. Hence the treatment of the second species of ectropion, he says, will never succeed so perfectly as that of the first, and the eyelid which will be drawn back shorter than natural, is prevented by the quantity of cicatrix which will follow. It is now that, in every case, the extension seems greater than it should be, in regard to the small quantity of skin lost or removed; for when the disease has once begun, though the contraction of the skin may be the cause of the turning of the eyelid, it is a different, with the turning of the eyelid, which never sets in motion, at last brings on a complete extension of the part. In those cases the eye may be misapprehended with the same as in extending to the same extent; to offer the finger's swelling of the external membrane of the eyelid has been cut off, and the edge of the part approximated to the eyelid, the shortening of the eyelid remaining after the operation is not taken, that it will be considered as nothing in comparison with the disease and the consequence considered by the ectropion. However, therefore, the removal of the skin which would extend, and the consequent shortening of it, are necessary to prevent the turning again and turning of the eye if not removed, at least moderately, Scarpa directs the surgeon to cut away the internal membrane of the eyelid

lid, as already explained, so as to produce a line of adhesion on the inside of the eyelid. In irritable cases of ectropion, in which the lining of the eyelids has become hard and callous, Scarpa applies to the external eyelid, for a few days before the operation, a soft bread-and-milk poultice, in order to render the part flexible, and more easily separated than it could be after longer rigid state.

The division of the cicatrix which has given rise to the swelling and eversion of the eyelid, as Scarpa observes, does not procure any permanent change in the part, and consequently it is of no use in the cure of the present disease. We see the same eversion occur after deep and extensive burns of the skin of the palm of the hand and fingers, whatever pain may have been taken, during the treatment, to keep the hand and fingers extended, no sooner is the contraction than completed, than the fingers become prominently bent. The same thing happens after extensive burns of the skin of the face and neck. — FARRIES, an Achromaticist, who well knew the necessity of making a small scar cut in the skin of the eyelid, for the purpose of reducing the cicatrix and external tumour, as the best expedient, to correct them, with sufficient pleasure, applied to them and the eversion, and lost sight of together. Whatever advantage may result from this practice, the same degree of benefit may be derived from using, for a few days, a bread-and-milk poultice, afterwards dry eversion, and lastly, the cutting based, as we get on, to divide the shortened eyelid in an opposite direction to that produced by the cicatrix; a position which Scarpa thinks should always be successfully tried before the operation is determined upon.

The surgeon, with a small convex-pointed bistoury, as he pulls an incision of sufficient depth into the internal cicatrix of the eyelid, along the tarsus, carefully avoiding the situation of the palpebral lachrymæ. Then with a pair of scissors, he should raise the flap of the divided lachrymal membrane, and continue to divide it with the bistoury from the deepest parts all over the inner surface of the eyelid, as far as where the tarsus passes this part, to be continued over the front of the eye, under the name of conjunctiva. The operation being thus accomplished, the membrane is to be raised still more with the Scissors, and cut off with one or two strokes of the bistoury, at the lowest part of the eyelid. The conjunctival bandage, to keep the eyelid opened, as it is applied as above directed. On changing the dressings, a day or two after the operation, the eyelid will be found, in a great measure, relaxed, and the disarrangement which the disease caused greatly avoided. The operation is rarely followed by bad symptoms, such as swelling, violent pain, and inflammation. However, should they occur, the bleeding may be relieved by means of an opiate (Opium), and as for the pain and inflammation, attended with a great obstruction of the eyelid opened upon, these symptoms may be cured by applying a poultice, or bags filled with moistened linen, as the same time applying internal anodynes, until the inflammation and swelling have subsided, and suppuration has commenced on the inside of the eyelid on which the operation has been done. After this the treatment is to consist in washing the part twice a day with warm water and vinegar, rose, and honey, in washing the wound a few times with the aqueous solution, in order to keep the cicatrization within certain limits, and to form a permanent cicatrix, proper for restoring the eyelid against. — (Scarpa and Malabarghi 1784.)

In cases in which the eversion is considerable, Mr. W. Adams has never found the simple division of the cicatrix, as practised by Scarpa, sufficient to effect a radical cure, and he therefore tried a new radical operation. In his first attempts, as employed a very shallow curved bistoury, the point of which he directed along the inside of the eyelid, in the outer angle, symmetrical and upwards, as far as the point of reflection of the conjunctiva would allow. Blotting passed it through the whole substance of the eyelid, and the integuments, and cut upwards through the tarsus, making an incision nearly half an inch in length. With a curved pair of scissors, he next supposed a piece of the edge of the tarsus, about one-third of an inch in width, and he afterwards removed with the same instrument the whole of the diseased conjunctiva. When the bleeding had ceased, Mr. W. Adams passed a needle and ligature through the whole substance of the eye divided por-

tions, and brought them as accurately into contact as possible. Finding, however, that the depth of incision had been left at the lower part of the cicatrix, he employed in future operations, instead of the curved, a pair of straight scissors, with which he cut out an oblong piece of the lid, resembling the letter V. Lastly Mr. W. Adams has tried an oblique incision to leave about a quarter of an inch of the lid adjoining its external angle, and after shortening the part removed in some way he brings the edges of the cicatrix together with a suture. — (See *Practical Surgery* above under Ectropion, &c. p. 1 and 2, Lond. 1812.)

On the subject of the foregoing proposal, Mr. Ross observes, "What Mr. W. Adams says, with a view of removing the whole of his eye method, about the frequent recurrence of cicatrix, when the conjunctiva is simply cut out, is a gratuitous assertion, contradicted by experience. I have already in a very great number of cases undertaken the cure of cicatrix in the common way — the operation always succeeded in such as the disease, or other circumstances of the disease allowed; and I have not yet observed any instance in a relapse." — (Farrès, *Gazette de Londres* in 1814, in *Parallèle de la Chirurgie Française avec la Chirurgie Française*, p. 384.) If this new operation, however, will cure the cicatrix, caused by the instrument of dissection, as its various directions, as proving great improvement, as the experience of Mr. Tardieu confirms (*Synopsis of the Diseases of the Eye*, p. 225), it is clear that though it may not be necessary in ordinary cases, in such cases will be entirely lost. Mr. Guthrie acknowledges that it may be highly useful in the cicatrix from the contraction of a cicatrix — (On the Operation Surgery of the Eye, p. 71.) The intended permanent cure of course is denied, as it is to the effect of prevention.

In the form of ectropion described by Mr. Guthrie as arising from a laceration, and contracted state of the lachrymæ of the eye, but without any cicatrix, he observes that the lachrymæ are, first, to remove the contraction of the skin externally; — 2dly, to remove and bring the eyelid to its proper situation, third, to neutralize curvature of the cartilage has been overdone, and the chronic inflammation removed. For fulfilling the first indication he recommends washing the external part with warm water, as to leave the skin as much as possible. It is then to be carefully dried, and respectfully anointed with the ung. oleo, for three or four days. Being thus protected from the atmosphere, it becomes softer, and it is a favorable state to yield to mild excitation. For accomplishing the second indication, Mr. Guthrie applies the sulphuric acid, the eyelid having been changed so as to prevent its slipping, the conjunctiva is to be gently wiped dry and everted as much as possible, so that the part where it begins to be reflected over the eyelid may become. An assistant is to raise the upper eyelid a little, and the patient is to look upwards. The third end of a constant silver probe is then to be dipped in the sulphuric acid and pushed over the conjunctiva, so that every part of it may be touched with the acid. The outer point of the probe is to be carried so far as where the lachrymæ begins to be reflected over the eyelid, but no farther. The palpebral lachrymæ, conjunctiva, and tarsus are to be treated; but the external angle, as well as every other part, except what is reflected over the eye, as to be carefully washed. The acid will then be applied, portion of the conjunctiva where; and in order to prevent the acid from affecting the eyelid, a stream of water is now to be directed over the eyelid with an elastic gun syringe. If the conjunctiva should not be turned sufficiently white, as supposition may be required. The use of the acid is to be repeated every fortnight; "and what applied in the manner directed it does not cause a slough, has a general contraction of the part, which is, however, only perceptible after two or three applications, by its effect in flattening the lid, which gradually begins to take place. After six or eight applications, the cure will be known that half accomplished, and in most cases of this species of cicatrix, the thickening of the conjunctiva will have subsided." The ung. oleo is to be constantly applied to the skin, and the ung. indur. 2dly, in the proportion of one part to four or six of the ung. oleo, is the edge of the eyelid. After the eyelid has returned two-thirds of the way towards its natural position, the interval between the applications of the acid must be longer, lest the contraction within the eyelid be carried too far, and it is to be repeated within

dead. After the operation is closed, the lips of the wound partly remain, and demand the use of the tag, by drag, stir, or other gentle stimulants.—*See* *Niemann's Chirurgische Heilmittel* (Engl. transl.) 2d. ed. cap. 6. *Richter's Anästhesie der Wundoperationen*, &c. 2. p. 473, &c. *Wunder's Manual de Plombage*. Gallie, *Lectures on the Operating Surgery of the Eye*, &c. Lond. 1822.)

ECZEMA, or *Erkema* (from *ekto*, to be out of), is characterized by an eruption of small vesicles on various parts of the skin, usually close or crowded together, with little or no inflammation except their bases, and unattended by fever. It is not contagious.—(*Baron's Synopsis*, p. 223, ed. 2.) There are several varieties of this disease, the most remarkable of which is the *eczema calycis* from the irritation of mercury. This form is attended with quickened pulse and a white tongue; but the stomach and bowels are not materially disturbed.—(*See* *Mercury*.)

EFFUSION, in surgery, signifies the escape of any fluid out of the vessel or vessels naturally containing it, and the sediment or portion which is the cellular substance, or in the substance of parts. Thus, when the skin is wounded, blood is sometimes effused from the vessels into the cavity of the wound; in cases of false aneurysm, the blood passes out of the artery into the interstices of the cellular substance; in cases of hernia or peritonitis, the serum flows from the bladder and enters into the cellular membrane of the peritonium and scrotum; and when great violence is applied to the skull, blood is effused even in the very substance of the brain.

Effusion also sometimes signifies the natural secretion of fluids from the vessels; thus surgeons frequently speak of the sanguineous lymph being effused on different surfaces.—(*See* *Exudation*.)

ELECTRICITY. Among the aids of surgery, electricity must hold a conspicuous and important situation. It has, however, but with a faint glow shined with remedies too much cooled up and too indifferently employed; that of having fallen into an undesired degree of neglect.

Whatever its effects may be on the system, it certainly possesses this advantage over other topical remedies, that it may be made to act on parts very remote from the surface.

Electricity, as a topical remedy for surgical diseases, is chiefly used in anæsthesia, hæmorrhage, some chronic irritations and abscesses, weakness from spasm, or convulsions, paralysis, &c.

In cases of suspended effusion, electricity is sometimes an important auxiliary for the treatment of the vital functions.—(*See* J. Curry's *Obs. on Effusion* (Engl. transl.) 2d. ed. 1815.)

ELEVATOR. An instrument for raising depressed portions of the skull.

Formerly the common elevator, now generally preferred by all the best operators, several others have been invented; as, for instance, the tripod elevator, and another which was first devised by M. J. L. Petit, and afterward improved by M. Loupe.

EMBRICATIO ALUMINIS. E. Aluminis ʒi. Acet. spiritalis roris leuissimæ, sig. Rec. For children and diseased joints.

EMBRICATIO AMMONIÆ. E. Liq. ammon. ʒi. Aluminis sulphurati ʒss. Sp. lavandulæ ʒss. M. For sprains and bruises.

EMBRICATIO AMMONIÆ ACETATÆ CAMPHORATA. E. Liq. camph. liq. ammon. acet. ʒss. ʒi. Liq. ammon. ʒss. M. For sprains, bruises and chilblains, not at a time of suppuration.

EMBRICATIO AMMONIÆ ACETATÆ. E. Liq. ammon. acet. liq. ammon. sig. ʒss. M. For bruises with inflammation.

EMBRICATIO CANTHARIDIS CUM CAMPHORA. E. Ther. canth. spirit. camph. sig. ʒi. M. This may be used in any case in which the skin is to be irritated. It should be remembered, however, that the absorption of cantharides will sometimes be so violent.

EMBRICATIO. (From *embere*, to be in, and *embere* out.) The operation of cutting hollows, in order to extract the fluids.—(*See* *Cantharides* (Emulsion).)

EMPHYSEMA. (From *emphos*, from *emphos*, to swell.) A swelling produced by air in the cellular substance. The common cause is a fractured rib, by which the vessels of the lungs are wounded, so that the air escapes from them into the cavity of the thorax. But as the rib is the nucleus of its being irritated, it is pushed the ribs and towards the pleura, which form the ribs and intercostal spaces, part of the air then necessarily passes through the pleura and the inserted muscles into the cellular membrane of the outside of the chest, and thence is diffused through the same membrane over the whole body, so as to irritate a considerable extraordinary degree. This affection of the cellular membrane has been commonly looked upon as the most dangerous part of the disease; but many circumstances will appear in the sequel.—(*See* *Emphysema*, *Med. Obs. and Inquiries*, vol. 2.)

Emphysema is most frequent after a fractured rib, because there is a wide laceration of the lungs, and so can let the air; it is less frequent in large wounds with a knife or sword, because the air has to pass and unimpeded issue; it is again more frequent in deep wounds with knives or small swords; but it is as common in many frequent in gun-shot wounds as the late Mr. John Bell supposed. (*On Wounds of the Chest*, p. 25, ed. 3, and, in fact, is not really so common as there are in cases of state, particularly where the ribs are not splintered.)

Emphysema has also been known to arise from a rupture of the larynx and trachea, produced by a blow or kick, as we find recorded in the case reported by Dr. S. Hoffman.—(*See* *Edin. Med. and Surg. Journ.* No. 72.)

The symptoms attending emphysema are generally of the following kind. The patient at first complains of a considerable tightness of the chest, with pain, chiefly in the situation of the injury, and great difficulty of breathing. The obstruction of respiration gradually increases, and becomes more and more insupportable. The patient soon finds himself unable to lie down in bed, and cannot breathe, unless when his body is in an upright posture, or he is sitting a little inclined forward. The countenance becomes red and swollen. The pulse, at first weak and contracted, becomes afterwards irregular. The extremities grow cold, and, if the patient continue undressed, he soon dies, in every degree of prostration exhausted.

The emphysema swelling, whenever seated, is easily distinguished from anæmia or anæmia, by the respiration which occurs on pressing it, at a time when the chest takes place on compressing a dry bladder half filled with air.

The tumor is extensive and free from pain. It does not of itself demand this depending parts, though it prevents it may be made to change its nature. The elastic, that is to say, it may be pressed down, but it rises up again as soon as the pressure is discontinued. The swelling never retains the appearance of the skin or the finger, or, in the language of surgery, never pits. The part affected is not heavy. The tumor has caused its appearance in one particular place; but it soon extends over the whole body, and causes an extraordinary distention of the skin.—(*See* *Edin. Med. and Surg. Journ.* No. 72, p. 431.)

The vessels of the pleura and intercostal may sometimes be so small to suffer the air to get readily into the cellular membrane, and irritate it, but may confine a part of it in the cavity of the thorax, so as to compress the lungs, prevent their expansion, and cause the same symptoms of tightness of the chest, quick breathing,

and sense of suffocation, which never does in the hydropneumothorax or empyema.—*Hewson*?

To understand why the air passes in all sort of directions, we must refer to the manner in which inspiration and expiration are naturally effected. In a well known, that is the perfect state, the struggle of the lungs always but in close contact with the pleurae, taking the chest, both in inspiration and expiration. The lungs themselves are only passive organs, and are quite incapable by any action of their own of expanding and contracting, so as to increase their external surface always in contact with the inside of the thorax, which is continually undergoing an alternate change of dimensions. Every particle that has any share in enlarging and diminishing the capacity of the chest, must contribute in the effect of adapting the volume of the lungs to the cavity in which they are contained, so long as there is no communication between the cavity of the pleura and the external air. If inspiration the thorax is enlarged in every direction, the lungs are expanded in the same way, and the air entering through the trachea, and the air vessels of these organs, prevents the occurrence of a vacuum.

But in cases of wounds, what there is a free communication between the atmosphere and inside of the chest, so sooner as the cavity expanded, than the air naturally enters it at the same time, and in the same manner, thus the air enters the lungs through the trachea, and the lungs itself remains proportionally collapsed. When the thorax is not contained in expansion the air is compressed out of the lungs, and also out of the bag of the pleura through the external wound, if there be a direct one; in which circumstance the emphysematous swelling is here effected.

But in the case of a fractured rib, attended with a wound in the pleura costalis, pleura pulmonalis, and *diaphragm* of the lungs, there is no direct communication between the cavity of the chest and the external air; in other words, there is no outward wound in the parietes of the thorax. There is, however, a permanent opening formed between the cavities of the lungs and the cavity of the chest, and two openings are between the latter space and the general cellular substance of the body, through the breach in the pleura costalis. The consequence is, that when the chest is expanded in inspiration, air rushes from the wound on the surface of the lungs, and enters itself between them and the parietal pleura. The lungs collapse in proportion, and the space which they naturally occupied when expanded, is now occupied by the air. When in expiration the dimensions of the chest are every where diminished, the air now lodged in the bag of the pleura cannot get back into the aperture in the collapsed lung, because there is already full of air, and is equally compressed every side, by that which is confined in the thorax. Were there no breach in the pleura costalis, this air could not now become diffused; the moment of inspiration would not enlarge the chest, remove the pressure from the surface of the wounded lung, cause air to be sucked out of it, as it were, and the space between the pleura costalis and pleura pulmonalis, and the process would go on till the lungs of the wounded side were completely collapsed. But in the case of a fractured rib or fracture of the chest, there is also a breach in the pleura costalis, without any free vent upwards for the air which gets out of the lung into the cavity of the pleura, as soon as the expiratory process lowers the capacity of the chest, this air, not being able to pass back through the breach in the collapsed lung, is forced through the laceration or wound, in the pleura costalis into the external cellular substance.

It is through the communicating hole of this structure that the air becomes most copiously diffused over the whole body, in proportion as the expiratory process continues to take care to lower the capacity of the chest, and passing the air, as it were, through the wound in the pleura costalis, immediately after it has been driven out of the wound of the lung in inspiration.—*See John Hall, On Wounds of the Breast, and the diaphragm, the Emphysema, &c.*

To prove that the communication of air in the chest is the cause of the dangerous symptoms attending emphysema, *Hewson* adverts to the histories of some remarkably cases, published by *Latre, Mery, W. Hunter, and Chevreau*.—*See Mem. de l'Acad. Royale des Sciences, p. 1712; Med. Obs. and Reports, vol. V, and Pathological Inquiries.*

In *Latre's* case, the patient, who had been wounded in the side with a sword, could not breathe without making the most violent efforts, especially during the latter part of his disease; he died on the fifth day.

In *Mery's* instance, the fourth and fifth ribs were broken by a sword passing over the chest; the patient's respiration was with singular force the first, and became more and more difficult till he died, which was on the fourth day after the accident.

In *Dr. Hunter's* case, the patient had received a considerable laceration on his side by a fall from his horse. He had a difficulty of breathing, which increased in proportion to the skin became elevated, and tense; it was to himself as well as to his friends. His inspirations were slow and almost instantaneous, and ended with a rush in the throat, which was produced by the shutting of the glottis after the least resistance to entrance without any pause, then suddenly opening the glottis, forced out his breath with a sort of gush, and in a hurry, and then quickly inhaled again, so that his respiration seemed to be to keep his lungs always full; inspiration attended expiration as fast as possible. He said, his difficulty of breathing was owing to an immovable tightness across his breast, and the pit of the stomach; he had a little cough, which accompanied his pain, and he brought up blood and phlegm from his lungs. He was relieved by scarifications, and recovered.

In *Mr. Chevreau's* case, the chest had received a laceration in the chest. He had a constant cough, bringing up, after many ineffectual efforts, a bloody discharge, heavily tinged with blood; he seemed to be in the greatest agony, and constantly threatened with suffocation. His pulse was irregular, and sometimes scarcely to be felt, his face livid, and when he was sitting, which was only very and then, he complained of a pain in his head. On passing a bandage round his chest, with a proper compress to prevent the discharge of air into the cellular substance, and to confine the motion of the thorax, the patient stated that he soon felt better. A strong compress on the hand also afforded him in the same way. notwithstanding bleeding, repeated scarifications, and other means, the state of suffocation and difficulty of breathing increased. On the fourth day, the air no longer passed into the cellular membrane, when on a sudden, striking his head back, which, as it were, for the admission of more air than usual, his breathing became more difficult and interrupted, he turned wholly insensible, and soon afterwards died.

Latre, Mery, and Chevreau opened their patients after death.

Besides a wound of the lungs and fractured rib, *Latre* found a considerable quantity of blood in the cavity of the pleura, and was sensible of some fluid air escaping as his first meeting the intercostal and pleura. The wounded side was hard and black, and the other side of the same color when inflated.

In *Mery's* patient no blood was extravasated, nor was there any thing preventing, except the fractured rib, the wound of the pleura, and that of the lungs.

Chevreau found a fracture of the tenth and eleventh ribs, and a wound of the lungs. The lungs before the wound were livid, and more congested than usual; but every thing else was natural, no extravasation, no inflammation, no internal emphysema.

Hewson made several experiments on animals, tending to prove, that air in their chests produced great difficulty in breathing, such symptoms in cases of emphysema; and in one case which he examined after death, air was actually discharged on separating the thorax.

The object of *Mr. Hewson's* paper is to explain the nature of the air in the chest, for the purpose of giving vent to the air confined in the cavity, but as it does for the discharge of air in cases of emphysema, of water in those of hydrothorax.

In writing of the lungs, says this author, whether occasioned by trauma, *etc.* or other causes, when symptoms of tightness and suffocation occur on, so far should we be from drawing the emphysematous swelling of the cellular membrane, that we should rather consider it as a favorable symptom, showing that the air is not likely to be confined in the thorax; and so he should we be from compressing the wound to prevent the inflation or emphysema, that we should rather dilate it (if not large enough already) or perform the paracentesis thoracis. We may judge of the necessity of this operation from the history of the Emphysema,

such as the aggrivated breathing, &c. For when these are not considerable, and the air passes out of the chest with sufficient freedom, the operation is then unnecessary.

If the disease is on the right side, the best plan for performing the operation, says Mr. Hewson, will be on the free part of the chest, between the fifth and sixth ribs; for there the integuments are thin, and in the case of air so depending drains is required. But if the disease is on the left side, it will be more advisable to make the opening between the seventh and eighth or ninth and tenth ribs, in order that we may be sure of avoiding the pleuro-peritoneum. A large penetrating vessel is inconvenient on account of the air entering by the aperture in such a quantity as to prevent the expression of the blood; a small vessel will be sufficient, especially as an does not require a large one for its escape. Mr. Hewson recommends dissecting cautiously with a knife, in preference to the common and hazardous method of thrusting a trocar.

There is one error prevailing in Mr. Hewson's paper, for which he has been justly censured by Mr. John Bell, viz. the idea that it is possible and proper to make the collapsed lung expand by making an opening in the chest. Bramwell and R. Bell have both imbibed the same erroneous opinion, and proposed plans for exhausting the air and expanding the lung. It is very certain that it is impracticable to make the collapsed lung expand, until the vessels in it are closed, and this closure is greatly promoted by the spast state in which the collapsed lung remains; a state also the most favorable for the absorption of any blood that the pulmonary vessels.

The true object then of making an opening in the thorax, which has purposes of aeration and relief, is not to obtain an expansion of the lung on the affected side, nor to take the pressure of the air from it; but to remove the pressure caused on the opposite lung by the distention of the mediastinum, and at the same time to diminish the pressure of the air on the diaphragm. The lung on the affected side must continue collapsed, and it is most advantageous that it should do so. The opposite lung is that which by a free vent of itself carry on respiration, and it is known to be fully adequate to this function, provided the quantity of air on the other side of the chest does not produce too much pressure on the mediastinum and diaphragm.

Mr. John Bell occasionally has remarks on this subject with avoiding the following passage:

1st. When the cracking (rattle) begins to turn over a fractured rib, small punctures should be made with the point of a lancet, as in bleeding; and if the point be struck deep enough, the air will rush out readily. But as supposing the lung is not adherent to the inside of the chest, this act was in the thorax, before it came into the cellular substance, it is plain that the thorax is still full; and that the lung of that side is surely collapsed and loose, and must continue so. The purpose, therefore, of making these scarifications, and especially of making them so near the fractured part, is not to relieve the lungs, but merely to prevent the air spreading more widely beneath the skin.

2d. If the air should have spread to very remote parts of the body, as in the scrotum and down the thighs, it will be easier to make small punctures in those parts, to let out the air directly, than to press it along the whole body till it is brought up to the puncture made on the chest over the wounded part.

3d. If notwithstanding these punctures and pressing out the air in this way, you should find by the oppression that either air or blood is accumulating within the cavity of the thorax, so as to oppress and the wounded lung, which was of course collapsed and loose from the first, into the diaphragm, and through the diaphragm to affect also the lower lung; then, a free incision must be made through the skin and muscles, with small punctures should be successively made through the pleura, in order to let out the air or blood contained in the thorax. (John Bell, *op. cit.*, p. 238.)

In all these cases, however, and frequently repeated, ventilation is generally proper.

After a few days the wound in the collapsed lung is closed by the adhesive inflammation, which the air no longer present out of it into the cavity of the chest, and the water round it may therefore be used. What air is already there is gradually absorbed; and the lungs expanding in proportion, restore the original situation.

The application of a bandage round the chest is more than granted in cases of emphysema; and its utility when the ribs are broken has been lately spoken of by Mr. Abernethy.—"Pressure by bandage (says he) not only renders the air from diffusing itself through the cellular substance, but serves to prevent a free escape of air of the wounded ribs, and of course diminishes the swelling of the wound, which would be increased by the constant transudation of air. Its great application, therefore, will often prevent a very troublesome symptom, while, at the same time, by keeping the fractured bones from motion it greatly lessens the sufferings of the patient." (Abernethy's *Surgical Works*, vol. 2, p. 179.) When emphysema is complicated with a fractured rib, the latter injury is unquestionably a reason in favor of a bandage. But whether the pressure of the roller will be useful or harmful with respect to the emphysema itself, or the state of the lungs and respiration, may be questioned. As to its tendency to moist the diffusion of air in the common vulgar language, this circumstance does not appear to us important, because the air, thus diffused, such as it diffuses the patient, is nearly harmless, at least as long as the interlobular texture of the lungs remains unaltered; a danger also which we have, as far as I can judge, less any tendency to prevent. Nevertheless a bandage will have no much effect in hindering the diffusion of air in scarifications, with this important additional consideration, that punctures or small incisions, made over the broken ribs, prevent the swelling of the air by letting it escape, while a bandage can only do so by retarding or lessening its escape from the cavity of the pleura; which mode of operation is sometimes would dangerously interfere with the promotion of respiration by the lung of the wounded side. At the same time, however, that when the air entered under the injured side of the chest is not in this quantity as to oppress the normal lung, and a rib is broken, a bandage will generally afford great relief. Indeed, it is his justice to Mr. Abernethy to state, that he does not recommend the employment of a bandage in all cases of emphysema. "Patients (says he) will be always be able to wear a bandage when one lung is collapsed, particularly if any previous disease has existed in the other, as it equally contains the nature of the rib on both sides, and in every possible enlargement of the chest, and necessary for the due extension of the air into the lung which still contains its functions. Under those circumstances, if the emphysema continues (and its continuance must always depend that the wound in the lung is not closed), I should esteem it the best practice to make a small opening into the chest, so that the external air might have a free communication with that cavity; and then the injured lung must remain motionless till no wound is healed, and the mediastinum will, in every way of the thorax, preserve its natural situation." (Abernethy, *op. cit.*, p. 153.)

The utility of a free incision and scarification is well illustrated in a case recorded by Larrey. The emphysema arose from a wound of the lungs by a lance. The whole body was prodigiously swelled, the integuments so distended that the limbs were inflexible, the eyes bulged, and the lips so enlarged that nothing could be introduced into the mouth. The pulse and respiration were scarcely perceptible, and the veins filled and interrupted. The lance had entered obliquely under the lower angle of the scapula, and through the muscles and internal surface of the wound were not parallel, the surgeons had applied adhesive strips, and closed the external opening. Hence the air, as it escaped from the lungs, distended the cellular texture. Larrey immediately removed the dressing, and with a lancet made the incision in the pleura and skin parallel. Clipping-glasses were then applied over the wound, and quickly filled with air and blood. The lips of the wound were now brought together, and kept so with a suitable bandage. Clipping-glasses and catheters were applied to various parts of the body, and in other incisions were made with a scalpel. The patient recovered. (Ope. Mem. de Larrey, *Médecine*, t. 1.)

Emphysema has been known to arise from the bursting of a vesicle, and absorption of the vesicle of the lungs; but the air which escapes in this instance cannot find its way into the cavity of the thorax, because the inflammation which produces the disease and absorption of the vessels closes those which are able

mem, and produces an adhesion of the edges of the wound or ulcer to the inner surface of the chest, so as entirely to separate the two cavities. We are not acquainted with any instance of the symptoms imparted to the confinement of air in the chest arising from disorganization and laceration of the surface of the lungs; but Parry, Dr. Hunter, and the author of the article *Emphysema* in the *Encyclopædia Médecine*, p. 100, have seen cases in which emphysema was imparted from abscesses of the lungs, attended with adhesions to the pleura, and sometimes in the situation of weak adhesions. In these instances, the air having made its way through the pleura and intercostal vessels, the air escapes also through the same track, so as to pass into the cellular membrane on the outside of the chest.

A violent effort of respiration has sometimes produced a certain degree of emphysema, which first enables its appearance about the clavicles, and afterward spreads over the neck and adjacent parts. The efforts of labour have been known to occasion a similar symptom; but no bad consequences attended. (*Medical Communications*, vol. 1, p. 176; Blackden, in *Arch. Med. et Chirurg.*, vol. 3; and Wilson's *Disc. on Strang.* p. 163.)

Lewis has described an emphysema of the throat, which, on account of its cause and the information furnished by it to the practitioner, is highly important. It took place in a young girl, who had suffered from a burn affecting her whole body, and he considers it as a pathological symptom of such an accident, denoting the existence of which it is so essential not to extend any further. (*See Blackden*.) It made its appearance on both sides of the neck, above the clavicles, and came on suddenly on the third day after the accident. The inspection of the body proved that the lungs and mediastinum were also in an emphysematous state. The rupture of the air, confined by the burnt body, passed, says Lewis, in vain attempt to expire, and especially when the violent fits of coughing occurred, a strong propulsion of this fluid towards the surface of the lung into the vesicular substance of the vessels. Thence the air passed into the cellular texture which unites the surface of the lung to the pleura pulmonary; and by extravasations from cells by cells it caused a spongy swelling of the cellular substance between the two leaves of the mediastinum. The emphysema increasing, at length made its appearance above the clavicles. The translocation of the lung and surrounding parts, in consequence of air passing into their vesicular and cellular texture, is an evident cause of suffocation, and the swelling seems so trifling as effect on the compression of a foreign body at the trachea, that one can hardly fail to look it on as essential symptoms, though an author has made mention of it. (*Blackden* in *Arch. de Med.* t. 4, p. 46.) The emphysematous swelling, sometimes formed in the axilla in the relaxation of a dislocated shoulder (*see Dislocation*), was pointed out by Desault and Ricard on the same principle as the swelling case, viz. a rupture of one of the vessels by the patient's efforts to hold his breath during the relaxation of the body. Here fail the explanation of the cause may be true has been questioned (*see Arch. de Sciences*, vol. 1, p. 11); the fact, however, admits of no doubt, and is both curious and interesting.

The example lately recorded by Dr. Ireland in one of idiopathic emphysema following pneumonia, traces as strong a resemblance to the case here cited from M. Lewis, that I cannot refrain from expressing that it may have been one of the same nature. (*See Trans. of the Royal and General College of Physicians*, vol. 1, art. 3.)

An erysipelatous swelling of the head, neck, and chest has also been noticed in typhoid fever. Dr. Huxham relates an instance of this sort in a soldier of a Scotch regiment. (*Medical Observations and Inquiries*, vol. 2, art. 3.) Another example as a case of bilious fever is recorded in a periodical work. (*See London Med. Repository*, No. 73.) A case of spontaneous emphysema is likewise described by Dr. Huxham. (*See Trans. for the Improvement of Med. and Chir. Knowledge*, vol. 1, p. 30.)

A curious example of what has been called a spontaneous emphysema is recorded by Mr. Allen Jones. The patient was a strong, athletic man, who about six years previous to his application to the Royal Infirmary, had received a smart blow on the neck from

the head of a post. This injury was soon followed by the formation of a fistula, issuing from the place which had been hurt. The swelling increased very slowly during the five years immediately succeeding its commencement; but during the week it entered a very rapid addition to its bulk. At this time it measured nearly six inches in diameter, seemed to be confined by a firm and dense covering, and the internal parts had undergone fixation. From the first to the last the manner had been productive of very little pain.

Being, from the apparent fluctuation that the tumour was encased, it was removed at a consultation to penetrate the swelling, draw off its contents, and then pass a seton through it. My plunging a lancet into it only a very small quantity of blood, partly coagulated, and partly fluid, was discharged—a quantity so trifling that after the operation, the use of the tumour was not perceptibly postponed. A seton was passed through the swelling. At this time the man was in perfect health.

About ten days after the operation, the patient was seized with extremely violent rigors, followed by heat, thirst, pain in the back, excessive pain in the tumour, and oppressive anorexia.

An emetic was prescribed, but instead of producing vomiting it operated as a cathartic. To remove the rigors the seton was withdrawn. The pain in the tumour, however, and the painfulness of the tumour, continued to increase, and thirty hours subsequent to making the puncture, air began to issue from the neck of the seton, and afterward the cellular membrane of the neck, and of the outer parts of the body in succession, became distended with a gaseous fluid. In the course of a few hours after the commencement of the general emphysema the patient died.

Ten days before death, when the body was first from putrefaction, it was opened. The emphysema was further increased and distended, some dark, and some clear, and was formed of its vessels, when the system was distended the size of the head of an adult. Even the cavities of the heart, and the cavity of the blood-vessels, contained a considerable quantity of air. We could discover no direct communication between the tumour and the trachea or lungs, although each was carefully sought for. (*J. A. Burns on the Surgical Anatomy of the Head and Neck*, p. 66—53.)

From such cases we may infer, that the preceding writers, that from the mere rupture of a line of the bronchial tube, occasioned by irregular action of the lungs, or by other external cause, a spontaneous distension of air may take place in the cellular texture of the body. Both examples are dependent on the same cause as the emphysema from injury of the lungs; only the rupture of the bronchial tube in the former cases is more obvious.

A general emphysema is sometimes seen in cases of gangrene. Here, however, it is hardly necessary to observe, the air is the product of putrefaction, and the former has not the smallest connection with any injury, or disease of the air-vessels of the lungs.

That very extensive emphysema does occur during the putrefaction process, without fracture, or punctured wounds of the lung, is a fact familiar with every medical practitioner whose opportunities are considerable; and it is equally well known, that this kind of emphysema is not attended with any dangerous consequences. It sometimes arises from a rupture of one or more of the air-vessels by the efforts of the patient to hold his breath.

In the *Maryland Medical Recorder* for January, 1808, a case of spontaneous emphysema is reported by Dr. Vesley, occurring in a child of 4 years old, which proved fatal in a few days. It is so to be regretted that paroxysms and suffocations were not resorted to, to relieve being placed on opiates and spastics, which failed to produce any improvement in the situation of the disease. Dr. Jackson suggests that possibly the disease arose from an accidental opening of the bronchus and involving membrane of the lungs, by which the air escaped and thus formed its way throughout the body. (*See*.)

Observations and Inquiries*, vol. 3. *Mém. de l'Acad. Royale des Sciences*, for 1712. Dr. Hunter, in *Med. Obs. and Inquiries*, vol. 2. *Carton*, in *Pathological*

would be necessary to open the thorax itself. Galea, however, imagined to measure the breadth, without making any such opening, and he expressed an opinion that he should be able to effect a cure. Not thinking the bones so extensively diseased as was apprehended, he pronounced the suppuration benign. After the removal of a portion of the bone, the chest was quite exposed (as is already by reason of the perforation having been destroyed by the previous disease). After the operation, the patient experienced a speedy recovery.

1. L. First case with an abscess in the anterior mediastinum. A consequence of a gunshot wound in the situation of the abscess. The cavity had been merely closed with some clothe's application; no dilatation, nor any particular evacuation of the wound had been made. The patient, after being in an apartment three weeks, and having his regiment again, was sent back in with irregular diarrhoea, and other febrile symptoms. Post opened the wound, and found the true abscess. As there was a difficulty of breathing, he suspected an abscess either in the diaphragm or below the diaphragm; and, accordingly, he proposed laying the bone bare and applying the trepan. The operation gave rest to some tedious cough; and as soon as the true part of the abscess was perforated, a quantity of pus was discharged. The patient was relieved, and ultimately recovered. (*Phil. Trans. for Med. Char. t. 1, p. 98*.)

Another instance, in which an abscess behind the sternum was cured by making a perforation in the bone opposite the lower part of the cavity in which the matter collected, is recorded by De la Mairiade—(*Ann. de Chir. et de Méd. t. 15, 167, 168*.)

When, in consequence of inflammation, an abscess forms deeply in the substance of the lungs, the pus more easily makes its way into the air-vessels, and tends towards the bronchæ, close towards the surface of the lungs. In this case the patient, upon opening the cavity, when the opening by which the abscess has burst internally is large, and the pus escapes from it in considerable quantity at a time, the patient is in some danger of being suffocated. However, if the opening be not immediately large, and the pus wound is difficult to get the pus out, a recovery may ensue. Abscesses in the substance of the diaphragm, and collection of matter in the liver may also be discharged by the pus being coughed up from the trachea, when the parts adjacent become connected with the lungs by adhesion, and the thickness of the liver are absorbed on its convex surface. When the collection of matter in the liver occupies any other situation, the abscess frequently makes its way into the veins, and the pus is discharged with the blood. Several cases of this kind are related by authors; but the most remarkable two in the *Medical Observator*, by De Haen makes mention of others, and Pambour, in his book on the frequency of the Abscess of the Liver, p. 24, relates sufficient instances of a similar nature.

I shall now proceed to the consideration of empyema merely so called. Sometimes it is a consequence of a penetrating wound of the chest; occasionally it proceeds from the bursting of one of those vessels; in a few examples it arises from the pneumoniae, in which abscesses of the liver burst (*Ann. de Méd. t. 2, p. 17*; *Mem. med. t. 2, art. 4*) but in the greater number of instances it originates from pleuritic inflammation, especially that of the empyema first.—(*Boyer, Traité de Méd. Chir. t. 1, p. 303*.) Empyema very rarely takes place in both sides of the chest, but is almost always limited to one side of the pleura.

According to Boerhaave, when empyema arises from pleuritic inflammation, pleuritis, or pneumonia, the symptoms characterizing it are always preceded by those of the disease, of which the effusion of pus upon the diaphragm is the effect. Dryness, thirst, therefore, increase whether the patient has pleurisy or pneumonia; the symptoms of which have lasted longer than a fortnight; and when, after a transient alleviation, there then flows constant diarrhoea, followed by a low, continued fever, with slight exacerbations. Notwithstanding these circumstances, Boerhaave holds, that the inflammatory disease has terminated in suppuration, and that the suppuration allowed the effusion of pus upon the diaphragm in the chest. Some of these arise from the mechanical action of the pus upon the lungs, heart, and portions of the chest, and being also in other effusions in the thorax, the rest may be

used to be the effects of inflammation and suppuration of the parts on the internal pleura, and therefore, particularly looking in empyema.

First, of the common symptoms, respiration is difficult, short, and frequent; the patient suffers great oppression, and experiences a sense of suffocation, and of weight upon the diaphragm. He cannot move about; even for a short time, without being quit of breath, and distressed with syncope. He has an almost incessant and very fatiguing cough, which is sometimes dry sometimes attended with expectoration.—(*Boyer, Traité de Méd. Chir. t. 1, p. 303*.)

No surgical writer with whom I am acquainted has treated with more discrimination, than Mr. Keen, Sharp of the symptoms produced by collections of matter in the chest. He remarks, that it has been almost universally taught, that when a fluid is extruded into the chest, the patient can only be, on the downward side, the weight of the accumulated fluid on the mediastinum producing trouble; and if he places himself on the upward side. For the same reason, when there is fluid in both cavities of the thorax, the patient finds it hard easy to lie on his back, or so turn forward, in order that the fluid may neither press upon the mediastinum nor the diaphragm. Now it is noticed by Mr. Keen, that however true the doctrine may prove in most instances, there are a few in which, notwithstanding the extrusion, the patient does not experience of more inconvenience in any posture than another, nor even of any great difficulty of breathing.—(*See De Bruns's Obs. III, and Monro's, &c.*)

In this account, observes Mr. Keen, it is sometimes less easy to determine when the operation is necessary, than if we had so exact a criterion as we are generally supposed to have. But, says he, though this may be wanting, there are some other circumstances which will generally guide us with a reasonable certainty. He states, that the most infallible symptom of a large quantity of fluid in one of the cavities of the chest, is a permanent expansion of that side of the chest where it does lie, in proportion as the fluid increases; and will necessarily elevate the ribs on that side, and prevent those ribs contracting so much in expiration as the ribs on the other side. This change is said to be most evident when the surgeon views the back of the chest.—(*Boyer, vol. vi, p. 357*.) Mr. Sharp also refers to De Bruns's Obs. III, vol. I, in order to prove that the pressure of the fluid on the lungs may sometimes be so great, as to make them collapse, and almost totally obstruct their function. When, therefore, says Mr. Keen, the thorax becomes thus expanded after a previous pulmonary disorder, and the case is attended with the symptoms of a suppuration, it is probably owing to a collection of matter. The patient, he observes, will also labour under a continual low fever, and a particular anxiety from the load of fluid.

Resolving the situation of the cavity by an accumulation of the fluid, the patient will be sensible of an induration, which is sometimes so evident, that a bystander can plainly hear it in certain motions of the body. Mr. Keen adds, that this was the case with a patient of his own, on whom he performed the operation; but the fluid in this instance, he says, was very thin, being a smooth matter rather than pus. Sometimes, when the practitioner applies his ear close to the patient's chest, when this is agitated a noise can be heard like that produced by shaking a small cask not quite full of water.—(*See Dr. Jenner's Case, on Fracture of the Pelvis, &c. of the King's and Queen's College of Physicians in Ireland, vol. 5, p. 6*.) In this instance the fluid resembled water.

According to the same author it will also frequently happen, that though the skin and superficial vessels are not inflamed, they will become enlarged in certain parts of the thorax; or, if they are not enlarged, they will be a little thickened; or, as Boerhaave, the intercostal spaces are enlarged, and when the suppuration is considerable, instead of being depressed, as they are in this person, they project beyond the level of the ribs.—(*Med. Chir. t. 2, p. 287*.) These symptoms, joined with the enlargement of the thorax, and the preceding collection of the pleura of lungs, were unquestionably in favour of the propriety of the operation. On observing Mr. Keen, among observations to recommend it upon such emergency, this is one, that if the operation should resemble the case, on account of the water which would neither be very painful nor dangerous.—(*See*

Critical Inquiry into the Present State of Surgery, vol. vi. Emphyema.

"This difficulty of lying on the side opposite to the collection of pus," says Le Den, "is always accompanied a sign of an emphyema. This sign, indeed, is in the affirmative; but the want of a dullness does not prove the negative; however, when there is adhesion of the lungs to the mediastinum, the patient may lie equally on both sides." (*Le Den's Obs.* p. 198, edit. 2.) The explanation of this circumstance offered by Le Den is, that when the cyst, in which the matter is contained, is between the mediastinum and the lungs, the mediastinum gradually yields to the volume of the pus in proportion as it is formed, and the cyst, in which it is contained, becomes dilated; "whence habitually becomes a second nature." Whereas, in an emphysematous person, in which the lung is not adherent to the mediastinum, and who lies on the side opposite to that in which the collection of pus is situated, the mediastinum is on a sudden loaded with an unusual weight of fluid—(P. 111.)

Internal contractions, that the difficulty of breathing which patients with emphysema find in the chest, sometimes lie lying upon the side opposite to that on which the disease is situated, never originates, as has been repeatedly taught and believed, from the fluid pressing upon the mediastinum and opposite lung—"I have (says Le Den) produced artificial cases of hydrothorax, by injecting water into the thorax of several dead subjects, through a trocar made in the side. This experiment can only be made on subjects in which the lungs are not adherent to the parietes of the chest; by this way from three to four pints of water were introduced. I then carefully opened the opposite side of the chest; the ribs and lungs were removed, the mediastinum could be distinctly seen, pushing from the vertebrae to the sternum, and supporting, without yielding, the weight of the fluid, in whatever position the body was placed."

It is evident, then, that patients with thoracic emphysema lie on the diseased side, in order not to obstruct the dilatation of the sound side of the respiratory organs, one part of which is already in a state of contraction. It is for the same reason, and in order not to increase the pain by the motion of the inflamed pleura, that pleuritic patients lie on the diseased side. The same thing is observable in peritonitis; it is a rule, in all affections of the parietes of the chest.—(*Richardson, Young, Obs.* L. 4, p. 168, 169, edit. 2.)

It appears to me, that there may be some truth in the foregoing statement; but the experiments are far from being conclusive with respect to the assertion, that in cases of emphysema, hydrothorax, &c. the fluid on one side of the chest does not compress the opposite lung. In the first place the quantity of fluid is frequently much larger than that which Richard and Rogers, secondly, although the mediastinum may not be so yielded to as the weight of a liquid suddenly injected into one side of the thorax, yet it may do so by the gradual effect of disease. Thirdly, many of the pleuritic cases of emphysema were adverse to Richard's inference.

Although surgeons should be aware, that patients with emphysema can sometimes lie in any position, without particular aggravation of the difficulty of breathing, yet it ought to be distinctly understood, that the generality of patients with this disease cannot place themselves on the side opposite to that in which the collection of pus is situated, without their respiration being very seriously obstructed. Another circumstance also which deserves to be mentioned while we are treating of the symptoms of emphysema is, that the adhesion of the intercostal membrane is sometimes not confined to the thorax; we can find it more remote parts, as the same side of the body as the collection of matter.—Both the foregoing remarks are confirmed by an interesting case which was published by Mr. Hey.

Sept. 2, 1780, Mr. Hey was desired to visit John Williams, who had been ill ten days of the influenza. The patient was found labouring under a fever, attended with rough difficulty of breathing, and pain in the left side of the thorax. He was bed-ridden; Hicines were repeatedly applied to the chest, and he took little or no nourishment, with a smooth mixture to stay his cough. "He was immediately relieved by three leeches, especially by the application of the blisters; but repeatedly relapsed." At last he began to die, and he expired

with the utmost difficulty, and could not lie on the right side without danger of immediate suffocation."

Mr. Hey found the patient in the state just now described on the 12th of September. "His face, and especially his eyes, were a little swollen on the left side." The left side of the thorax was larger than the right, and the intercostal spaces, they said, distended, pressing the intercostal muscles, they said, distended, they yielded a little to a strong pressure, but rebounded again. The abdomen, especially in its upper part, appeared to be fuller than in the natural state.—(*Mr. Hey's Practical Obs. on Surgery*, p. 476.) This last symptom is also particularly noticed by Boyer.—(*Med. Chir. L. 7, p. 237.*)

Another remarkable symptom which is occasionally produced by collections of matter in the chest, is an alteration in the position of the heart. I have seen a patient in St. Bartholomew's Hospital, who had a large quantity of matter in the left lobe of the lungs, that it completely displaced the heart, which pulsated against the inside of the chest at a considerable distance to the right of the sternum. This matter he might perhaps have been cured had paracentesis thoracica been performed in time. Some supposed an aneurism from the throbbing on the right of the sternum, and the case was not fully understood till after death, when the body was opened. A little matter in the synchysis, however, might have occasioned any kind of mistake, understanding, that it was an aneurism, and that making an opening for the discharge of the matter affecting the only natural chance of preserving life. There had been pain and inflammation in the chest, relieved by leeches; there was very great difficulty of breathing; the heart, which ordinarily lies in the usual place, was displaced; but now pressed on the right side of the sternum.

That the heart should be displaced in this manner by very large collections of fluid in the right cavity of the thorax, one would naturally expect; but it is a circumstance that has not been much noticed by writers. Lewis, however, has related a highly interesting case, where the heart was not only pushed considerably to the right of the sternum, but its action was so much impeded by the displacement of its position, that the pulse in the large arteries was thereby rendered extremely feeble. In this instance, also, the diaphragm had descended so low down as to compress some of the small intestines into the cavity of the peritoneum.—(*Memories of George Milne, L. 2, p. 46, 50.*) Pott has also recorded an example in which a collection of fluid in the left cavity of the chest displaced the heart, the pulsations of which were perceptible between the third and fourth ribs of the right side, near the sternum.—(*Clinique Obs.* L. 4, p. 78.) Thus Boyer speaks of one case in which the displacement of the heart was so extensive that ex pulsation was felt near the right axilla.—(*Threats of the Med. Chir. L. 7, p. 237.*) In the same work also Mr. Blandin is also a proposition exhibiting the displacement of the heart into the right side of the chest, by matter in the left pleura, the left lung being nearly obliterated.—(*Lectures, Compt. de med. Muséum Ann.* p. 26, nov. 1786.) The heart is sometimes thus displaced by collections of fluid in the chest, and its pulsation is distinguishable in the epigastrium.—(*Hodgson on the Diseases of Arteries and Veins*, p. 95.)

When the cavity of the pleura contains fluid, and the surgeon strikes the thorax repeatedly with the ends of his fingers, a dull sound is said to be produced, quite different from what would occur were the chest in its natural state. But, as Boyer remarks, the symptoms, in which so much importance has of late been attached, being common to effusions in the thorax and several other diseases, will not draw us beyond, unless combined with other signs of emphysema. Nor will any useful information be derived from the above particulars, except the practitioner has had a good deal of experience in them, and they are repeatedly contrasted with the pulse in different positions.—(*Med. Chir.* L. 7, p. 237.)

The symptoms of emphysema are frequently very equivocal, and the existence of the disease is generally somewhat doubtful. Paracentesis pleurica is a case where the lung was displaced, at the same time that the thorax contained a considerable quantity of pus. Although the patient had been ill for two weeks, he had

suffered no difficulty in breathing, and had had only a slight cough. He then met with a case of nearly the same kind. A patient who had been for three days afflicted with a considerable dyspnoea and an acute pain on the left side of the chest, got somewhat better. He felt an unusual difficulty of breathing on whichever side he lay. The only thing which he complained of, was the sense of a fluctuation in his thorax, and a little constriction of his respiration. When he was in a sitting posture. These symptoms did not seem sufficiently decided to justify the operation, and it was delayed. The pleuritic symptoms continued, with cold sweat, and the patient died on the eighth day. Five pints of pus were found collected in the chest. (See Le Den's *Observations on Surgery*, p. 105, 123, vol. 2.)

The symptoms thus particularly depending upon suppuration, that is to say, upon the disease and suppuration within the abscess, we nearly the same as those which accompany all large deep-seated abscesses. The liver attending the disease is inflamed, but does not entirely crum. On the contrary, it soon changes into hectic, attended with flappings of the cheeks, heat of the pulse of the hands, and exaltations every evening and after meals. In the night, the upper part of the body are covered with perspiration; the patient is tormented with insupportable thirst. As appetite quite fails; the debility becomes extreme; he is subject to frequent fainting fits; diarrhoea occurs; and the liver itself becomes over-heated, shrunken, and of the yellow tinge observable all over the body. At length the blood, excrement and the latter Hippocratic vomit out, frequently attended with dried paper and coffee-colored urine, and sometimes with small pieces

In the operations of steamship and many other publicans relating to this subject, are omitted of its another part of this History from *Precursors of the Thomas*, it will only be necessary for us here to select a few of works, which may be advantageously consulted for references on engraving. A most peculiar case of emphysema occurred under the above observation, which was reported at length in the *Med. Record* for 1922. The patient had been treated by a number of physicians for asthma of the chest, from the circumstance of large quantities of gas passing off from the stomach and bowels at short intervals, and the pulmonary symptoms were attributed to the displacement of the diaphragm by the pressure of the enlarged lungs. On dissection, however, the case was found to be very grave, and so urgent for the purpose of this letter had taken place through the emphysema near the cardiac orifice of the stomach, whereby the stomach slipped itself into the anus, and the matter was thrown up from the stomach or passed on by the bowels.

I have now a patient in this city under medical treatment, who, I don't see, is suffering under any more

which sometimes, or rather often, its way into the stomach, probably by a similar force. Large quantities of gas are passing periodically from the bowels or are ejected from the stomach, which I now satisfied does not come from the liver, and I have no doubt this is the case with many cases treated as hepatic diseases.

Revue.

ENCANTHUS. (From *En*, and *anthos*, the stage of the eye.)

The similarity, at its commencement, to looking like a very large, but a small, red, and some times rather livid, eelworm, which grows from the cartilage, lacrymæ, and, at the same time, from the neighbouring semicircular fold of the conjunctiva. The lividness emanates from a considerable quantity; its ends extend beyond the cartilage, lacrymæ, and semicircular fold, to the neighbouring lining of skin on both eyelids. The patient experiences very different inconvenience from the origin, and interposition between the assumption of the eyelids, which it necessarily keeps asunder, on the eye, to the ends the

The parasite keeps up a chronic onslaught, impedes the action of the cystitis, and, in particular, prevents the complete closing of the ure. Besides, partly by compressing and partly by displacing the wall of the ureters laterally, it obstructs the free passage of the fluid into the ureter.

According to Suruga, the sclerite, as in *Aspeirosetis*, is coarsely granulated like a malley, or is of a rugose and fragrant structure. Afterward, when it has acquired a certain size, one part of it represents a granulated mass, while the rest appears like a smooth, whitish, or red-colored substance strewn with various yellow, sometimes appearing as far as the conjunctiva covering the side of the eye and to the nose, to where the cilia and sclerotic tube. In this undisturbed state, the conjunctiva constantly secretes the farinaceous lachrymation, the saliva vomitans, and the continuous lining of one or both eyelids. In addition to the roots, which in such circumstances connect the lachrymation with the caruncula lachrymalis, the semilunar fold, and the conjunctiva of the globe of the eye, the conjunctiva exists as appendage, or process, first elongation, along the inside of the upper or lower eyelid, in the direction of its edge. The middle or body of the conjunctiva divides near the cornea, as it were, like a crocodile's tail, to form two appendages or eyelashes, one of which extends along the inner surface of the upper eyelid by the margin of which it is covered, while the other shoots in a direction from the internal towards the external angle, along the inside of the lower eyelid, which also conceals it beneath its edge.

The body of the encaitheon, or that visible portion of the whole excystozoan which reaches from the cystic cuticular wall to the second transverse, and, usually, over the crenulations almost to the junction of the following with the second, sometimes forms a prominence as large as itself and is character. At other times it is of considerable size, but depressed, and, indeed, conical, as it were, at its center. Still, however, the body of the encystozoan possesses that prevalent appearance which prevailed in that whole era or both the zoogeographies on the inside of the cysts; it appears rather like a honey comb granulated substance.

On turning out the inside of the eyelids, these appendages or elongations of the cornea form a very marked prominence. When both eyelids are equally infected, and turned inside out, the appendages can usually be seen, as it were, a bag, the back of which lies on the globe of the eye.

Robinson's (1971) remarkable apertures a compressible integument. This character is caused by the dull, not broken, or (as Ross says) the thick redness of the cuticle, by an excessive hardness, and the limited space which occurs in it, and extend to the dorsal, the whole body, and the tongue, especially when the former has been slightly hooked. It is also caused by the porosity of the cuticle, to which, by the partial dilatation of its surface, which is a fatiguing operation, and is thin and exceedingly brittle, thereby. The disease is constantly attended with anæmia, and preceded by a venous plethora of the venæ.

The spinal and neighbouring bones, which are of a spongy texture, are said to participate very much in the disease, the latter of which also becoming evoked. — *Ann. Lett. et des Arts* August 1. 3. 1787, 3. 1. The same

of extensive early attacks of palliative treatment; no less, indeed, an effort be made to enlarge it entirely, together with the whole of what is contained in the orbit, and even then the eyes is salubrious.

These joints become in the treatment that the operation rarely proves successful, and admit that it is always followed by an incurable weakness, and a considerable extension of the lower eyelid—(Nec. cit. p. 180.) Fortunately, the truly cancerous encephalitis is uncommon; Mr. Guthrie has not seen it (*Operative Surgery of the Eye*, p. 177); and Mr. Turrell, who was a surgeon to the London Eye-hospital several years, never met with an instance of it—(*Synopsis of Diseases of the Eye*, p. 183.)

The benign encephalitis, however, which it may be, is always a deadly hydatid. Those instances which are small, compact, and granular, like a testicle, or of a fingered structure, which originate either from the caruncula lachrymalis, or the sclerotic part of the conjunctiva, or from both these parts together, and even in part from the lateral commissure of the eyelids, may be raised by means of a pair of forceps, and cut off from the whole of their origin, closely to their base, with the divided scissors with certain caution. In the performance of this operation, it is necessary to introduce a needle and thread through them, with care, as some are wont to do, for the purpose of raising it, and destroying more completely its origin and adherences. The same object is fulfilled by means of forceps, without introducing the patient with a puncture of this kind, and drawing a thread through the part in order to make a noose. However, in cutting out an encephalitis of this kind, care should be taken not to remove, together with that portion of the caruncula which originates from the caruncula lachrymalis, any more of this latter body than what is absolutely necessary for the precise eradication of the disease, in order that no irreparable weakness may be occasioned.

When the large encephalitis has been detached from all its roots, says Keegan, the eye must be washed several times with cold water, in order to cleanse it from the blood, and then it is to be covered with a piece of the linen, and a protective bandage. On the 2d, 3d, or 4th day, the inflammation arising from the operation usually ceases, and the suppuration from the wound is accompanied with the requisite appearance already described. The little vessels are then to be washed with a piece of linen, squeezed to a pulp like a crayon, and the vitreous collyrium, containing the residue of quack seeds, is to be injected into the affected eye several times a day. If these seeds should not bring about the wished-for, coagulating, but, on the contrary, the small vessels situated on the caruncula and internal commissure of the eyelids should become stationary and connect with great flesh, the caustic strychnine ought to be applied to them. The conjunctiva, however, should be avoided, as much as possible, especially if it is all removed. When the fungus granulations have been destroyed, the cure may be perfected by the collyrium already mentioned, or another by introducing three or four, between the eyelid and the internal angle of the eyelids, the powder of turp. and the Armenian bole. Before recommending powdered alkali, other signs of its cooperation with leech salve—(Encycl. Anat. Chir. Acad. 22.)

Excision is regularly applicable to the lachrymal sacculus, which is of considerable size, and bottom lies at its base, or which forms a prominence as large as a nut or almond, with two fleshy appendages extending along the inner surface of one or both eyelids. The application of a ligature is such an enormous weight to be required as a method of cure for the large lachrymal encephalitis never has a sufficiently narrow neck to admit of being tied. On the contrary, when the tumour is subcutaneous, its roots are usually joined to the caruncula lachrymalis, the sclerotic lid, and the conjunctiva covering the eyelid, adherent nearly as far as the corner. In this state also, the encephalitis has one or two fleshy appendages, which reach along the conjunctival lining of one or both eyelids. Hence, though the ligature were of service to a portion of the body of the encephalitis, yet if both the appendages would still remain to be excised. This would require not only high skill, but the knife. In this disease, there is no substance for the use of homocutaneous, in which the

adhesions for the ligature, which so much injury does; for many are removed of considerable substance, sometimes being removed, without the least material occurrence from loss of blood. To these, Keegan observes, he could add a good number of his eyes, so that no doubt can now be entertained as to this point.

Pellier relates a case, in which an encephalitis was followed by a dangerous leucorrhoea, though it had been cut out by an expert operator. He refers, however, into no detail concerning the nature of the complaint, nor the way in which the operation was performed; circumstances from which one might deduce the nature of this unusual accident. Indeed, the same author adds, "I have often performed this operation by such excision, and have never met with a similar phenomenon."—(*Revue d'Observ. sur les Maladies de l'OEIL*, part 2, vol. 118.)

When the encephalitis is large and extensive, with two extensive fleshy appendages, one on the inside of the upper eyelid, and the other on the outside of the lower, we are to proceed in the following manner. The patient being seated, an attempt is to turn out the inside of the upper eyelid, so as to make use of the appendage of the encephalitis project outwards. By means of a small bistoury, a deep incision is next to be made into the encephalitis, in the direction of the margin of the eyelid; and then having taken hold of and drawn it forwards with a pair of forceps, we are to separate it throughout its whole length, from the inside of the upper eyelid, proceeding from the external towards the internal angle of the eye, as far as the body or middle of the encephalitis. We are then to do the same in the lachrymal appendage on the inside of the lower eyelid.

Afterward the body of the encephalitis is to be divided, if possible, with a pair of forceps; but when the instrument will not answer the purpose, a fleshy body must be employed. This fleshy portion is not to be detached, partly with the bistoury, and partly with the curved scissors, from the sclerotic conjunctiva, on the globe of the eye, from the sclerotic lid, and from the caruncula lachrymalis; dividing the substance of the lid just above of less deeply, according to the depth and hardness of the large lachrymal encephalitis. There it is proper to state distinctly, that when we have to deal with an old large tumour of this nature, deeply rooted in the caruncula lachrymalis, it is not regularly in our power to procure a sufficient quantity of the substance of this part, to prevent the cure from dropping every the shock after the wound is healed.

The eye is to be repeatedly washed with cold water. The rest of the treatment consequent to the extirpation of a large encephalitis, is almost the same as what was explained in speaking of the small encephalitis. Belling, the eye very frequently in the lesion of mucous, and employing abstract, detergent collyria, as the best local means, with the utmost attention, according to expectation, has taken place on the surface of the eyelid. Then we may have recourse to gold and silver points and cautery. The mildest topical applications are generally the best, both in the first stage of suppuration, as well as afterward, particularly when, together with the encephalitis, we have removed a considerable part of the conjunctiva which covered the eyeball towards the nose, and was intimately connected with the body of the encephalitis.

 6. *Op. s.d.g. 107. Tinctura opii guttas xl.*—*Misc.*
 The two latter are particularly useful when phlegmatic exerts about the rectum, bladder, or uterus. They have great effect in dissolving spasmodic affections of the canal and the neck of the bladder.

Tubercle

Exposure in cases of unperforated hernia.
 6. *Nouveau* 1). *Ap. hernia* 3). The plug is to be introduced ten inches, and the ligure then removed for use. The ball should be first ejected, and one alternate the other, unless the glyster operate with dangerous violence, as it sometimes does in particular constitutions.

ENTEROCELE. (From *enteros*, the bowels, and *cele*, a tumour.) A hernia, the contents of which are intestine.

ENTERO-EPHLOCELE. (From *enteros*, the bowels, *ephloce*, the constrictor, and *cele*, a tumour.) A hernia, the contents of which are both intestine and omentum.

ENTEROTOMY. As Mr. Cooper has not introduced this operation into his Dictionary, it may be safely presumed that it has not been performed, at least with success, in Great Britain or on the continent.

Y^o Professor White, senior, of Berkeley Medical Institution, informs the honour of having first performed this operation, and with entire success, on May at the year 1850, for the extrusion of a loop from the intestine. This case, so novel and important, and standing as it does alone in this country as well as in Europe, will be found recorded in the *Med. Repert. of New-York*, *March* 5, vol. 4, p. 267.—*See*—

ENTEROPH. (From *enteros*, to turn.) An impression of the eyelids.—*See* *Protrusion*.

EPILOPHUS SHOT AWAY. The promise of General Larrey furnished a curious example, in which the epiglottis of a French soldier was shot off at the battle of Alcatraz, on the 23rd of March, 1811. The ball entered in the angle of the jaw, crossed the throat obliquely, and came out at the opposite side of the neck. The bone of the tongue was struck, and the epiglottis shot away; the patient spit it up after the accident, and showed it to the surgeon who first saw him.

The patient was not in much pain; but his voice was hoarse, feeble, and scarcely audible.

When he first attempted to swallow, he was seized with a convulsive suffocating cough, attended with vomiting. Annoyed by these, which the extreme heat of the weather, and the irritation of the wound excited, he incessantly repeated his attempts to drink, but always with the same result. Four days were passed in this deplorable condition. He already expressed violent complaints in his stomach, continued loss of sleep; he had a small scorched palate; and was beginning to lose flesh.

Such was the state of this wounded soldier, when Larrey saw him on the 18th day. After making a few inquiries about what had passed after the accident, attempting to make the patient drink, and examining the injury of the wound, Larrey was convinced that the possibility of suffocation and the inability to swallow, depended upon the parts being opening of the gullet, the lid of which had been shot away. The prognosis of the injury was accordingly favourable, and there can be no doubt, that if the patient had been abandoned to the resources of nature, he would have died in the course of a few days. The indications were equally difficult to fulfil. He went, spirit was to appease the hunger and thirst with which this poor soldier was afflicted. Larrey immediately was provided with up clean gun-time, constructed for the epiglottis. This instrument was introduced with the usual precautions into the pharynx, and by means of it the patient was given some drink, which relieved his thirst, and afterwards some rich food. The patient was led in the evening for six weeks, at the end of which time he was able, without the assistance of the tube, to swallow much purely, and thickened fluid made of pure milk. The powers of speech and deglutition at time became much more perfect; at intervals, as Larrey informs, of an enlargement of the external cartilage, and an expansion of that part of the tube of the instrument which lay next to the pharynx. Larrey found a series

valuable for the epiglottis.—(*Mémoires de Chirurgie Militaire*, t. 2, p. 145.—148.)

The foregoing case demands, in a convincing manner, the importance and utility of elastic gum tubes for obviating constriction and mediating down the impingement in wounds about the throat. All practitioners, and especially military surgeons, should be duly impressed with the necessity of having such instruments always at hand. The patient, whose case is above related, owed his preservation altogether to this means, without which he must have been starved to death.

In the 4th vol. of the above work, p. 217, is recorded another case, in which a gun-shot wound, that took away the epiglottis and broke the external cartilage, was successfully treated.

EPIPHORA. (From *epiphora*, to carry with force.) By this term is meant an accumulation of tears on the inner part of the eye; in consequence of which, the person affected is not only under the necessity of frequently wiping them away, but vision is injured by the morbid effusion, which they produce of the eye of light that over the eye. *Epiphora* is distinguished by modern writers from *epiphora*; the cause of *epiphora* lies in water obstructed in the absorption and conveyance of the tears from the lacrymal into the sea. *Epiphora*, on the other hand, consists in a superabundant secretion of tears, and is a disease of the secretion, not of the conveyance of the lacrymal organs.—(*See* W. H. Adams's *Medical Essay on the Diseases of the Lacrymal Organs*, p. 47, 48, *Loc. cit.* 1814; and *Beer, Lehre von den Augenkr.* t. 2.)

EPIPHORE. (From *epiphora*, the constrictor, and *phore*, a tumour.) A hernia, formed by a protrusion of the constrictor.—*See* *Hernia*.

EPHILIS. (From *ephilios*, and *phile*, the given.) A small tubercle on the gums. It is said sometimes to become cancerous. The best plan of cure is to cauterize it with a stick.

EPHILIS. (From *ephilios*, to irritate.) The state of irritation, attending the early stage of acute dysentery. Mr. Ferrius has described a state of the constitution produced by malarial action as it is a poison. He calls it the malarial miasm, and mentions that it is characterized by great depression of strength, anxiety about the precordia, irregular action of the heart, frequent sickness, trembling, a small quick, sometimes intermitting pulse, occasional vomiting, a pale, contracted countenance, a cold, if coldness; but the tongue is seldom firm, nor are the vital and natural functions much disturbed. In this state, as in the case of malarial fever, Mr. Ferrius advises, with a view of preventing the dangerous tendency of this affection, the immediate discontinuance of the use of mercury, and exposing the patient to a dry, cool air. The important criterion may often be ascertained by the cough, vomiting and large doses of ammonia, if necessary he also left off. *Epiphora* is also benefited, when the stomach will bear it.—(*Praxis en Luc. Viroto*, p. 156, &c. 1813.)

ERYSIPELAS. (From *erys*, to drive, and *ipe*, to swell.) St. Asclepius's erys, so called, from its tendency to drive the neighbouring parts into the same state, or, in other words, from its propensity to spread.

Erysipelas may be defined to be a catarrhus inflammation, attended with redness, which discolours, and leaves a white spot for a short time after being coated with the red of the finger, and the affection, which is irregularly circumscribed by a defined line, is characterized by a remarkable propensity to spread.

The part is generally of a bright red colour, clear, and shining. The disease is not accompanied by throbbing; and a burning heat and tingling are felt rather than acute pain. If the skin above be affected, there is hardly any perceptible swelling, and no tension; yet some difference is perceived between the sound and the inflamed part by passing the finger over it. In many instances, vesicles arise; a crustaceous which left Dr. Wilson to scratch the disease in the order of the finger. However, if we mean this arrangement to be referred to what is named local or accidental erysipelas, as well as to the idiopathic form of the disease, there cannot be a doubt of its immaturity; many examples of erysipelas from local erysipelas being characterized by a more or less immaturity.

However, the treatment of erysipelas has

Mr. Pearson divided the complaint into three forms, viz. phlegmonous, indurated, and gangrenous.—(*Principles of Surgery*, chap. 11.) In various authors, 1. The idiopathic, or primitive erysipelas, or that which arises spontaneously from an internal cause, is regarded by many other diseases. 2. Erysipelas, or secondary erysipelas, depending on another affection by which its progress is completely influenced. 3. Accidental erysipelas, or that which is usually excited by some external morbid cause.—(*Lancet*, Med. Press, &c., 2, Nov. 1848.)

The division adopted by Mr. Lawrence is into erythema, simple, indurated, and phlegmonous erysipelas. By erythema, he understands inflammation of the skin, either alone, or in conjunction with that of the subjacent adipose and cellular tissues. Like other inflammations (he says), it varies in degree. When it affects the surface of the skin, which is red, not sensibly swollen, soft, and without exudation, it is called erythema. Simple erysipelas is a more violent cutaneous inflammation, attended with effusion into the cellular substance, and generally with redness. Phlegmonous erysipelas is the highest degree of the affection, involving the cellular and adipose membrane, as well as the skin, and causing suppuration and destruction of the tissue.—(*The Med. Clin. Trans.*, vol. 11, p. 7.) When erysipelas, however, is defined to be inflammation of the skin, a peculiar kind of inflammation would be implied; for the skin, like all other parts, is often the seat of common inflammation. My view of the subject lead me to consider erysipelas as a compound of an inflammatory nature.

In the phlegmonous erysipelas, the skin is more raised than in the simple form of the complaint, the swelling is harder and deeper, and of a darker colour. The redness has often a brownish or dark lead tint; and the discoloration is important inasmuch, giving to the part a marbled appearance. The tumescence is more considerable than in simple erysipelas, the whole depth of the adipose and cellular contents being loaded with effusion, so that the part, or leg, appears of twice the natural size. The sensation of heat and pain, at first sight, is exaggerated to a very severe degree, and may be accompanied with throbbing. The affected part at first yields slightly to the pressure of the finger, but subsequently becomes tense and firm. Vesication, often minute and watery, rises on the surface with purple contents; but sloughing of the cellular membrane soon comes on, and the glands syphilitic are agitated. According to Mr. Lawrence's observations, pain, however, is not attended with increased swelling, elevation, and pointing, as in phlegmon; on the contrary, there is rather a diminution of tumour, a subsidence, and a loss of surface in the part. At first, the cellular texture contains a watery-like or wheal-like matter. The fluid gradually becomes yellow and purulent, and we often find it presenting all the characters of good pus, and very thick. The serum is diffused through the cells at an early period, and a mixture of serum and pus often fills a considerable portion of the cellular texture, without any distinct boundary. Frequently matter is deposited in small, separate pockets, forming a kind of little abscesses, which often run irregularly in the cellular texture. The substance turns grey, yellowish, or tawny; and sometimes appears like a dirty, spongy substance, filled with a turbid fluid, very heavy in viscosity, and when it is converted into more or less considerable fibrous streaks, of various size and figure, which some way soaked with matter like a sponge. The integuments over a large slough of this kind being deprived of their vascular supply, become cold, and often lose their quality. The suppuration and necrotic processes go on to a great extent when an entire limb is affected, sometimes completely denuding the skin, and often separating it through a large space, occasionally penetrating deeper, passing between the muscles, causing inflammation of them, separation between them, and often sloughing of the muscles. When the substance of a leg is thus generally inflamed, the pain is not escape; inflammation of the external membrane, effusion of matter into the skin, and elevation of the cutaneous membrane.—(*See Harrison's Practical Obs.*, p. 115, vol. 2; and *Lancet*, Med. Press, &c., 2, Nov. 1848.) An inflammation of such extent and violence cannot fail to produce the most serious derangement of the nervous system, typhoid symptoms, inflammation of

the lungs, or pleura, of the arterial system with haemorrhage, &c.; and the case is usually fatal. If, however, says Mr. Lawrence, the patient should recover after intense suppuration and discharge of slough, the parts which have been inflamed are so changed in structure, and the skin, fascia, muscles, tendons, and bones are so materially agitated and fixed after the extensive destruction of the connecting cellular texture, that the motion of the part is permanently and severely injured.—(*See Lawrence, in Med. Clin. Trans.*, vol. 11, p. 12.)

The following is Mr. Lawrence's description of simple erysipelas. The skin is precariously red and shining, having a light or rosy tinge in the early stage and slight elevation of the affection; when, in some languages, it has received the popular appellation of the rose; while, in other instances, it is of a bright scarlet, or even a deep and livid red. The cellular discharges are profuse, resembling at first the process is morbid. If the skin alone be affected, there is hardly any perceptible swelling, and no tension; but some difference is perceived between the inflamed and the unaffected part, by passing the finger over it. Erysipelas, however, is fixed by Mr. Lawrence to be confined to the skin, except in the slightest cases, effusion soon takes place into the cellular texture, causing a soft swelling; and this may be considerable, together with much tension and a sterner surface, when a large part of the body or an entire limb is involved. The inflamed part is hot and painful, at first a stinging or itching is felt, which soon becomes smarting, and burning sensation, with much pain is present. The pain is not so intense and burning as in phlegmon, nor is it attended with throbbing. This kind of inflammation often ends by resolution; the process and other symptoms disappearing, and the skin recovering its natural state, with or without a separation of the vessels. Frequently suppuration takes place from the inflamed surface, elevating the cellular tissue smaller or larger vesicles, or little bubble-like tumours produced by lentils, or rising to a boil, yellow, jelly-like deposits, which remain slightly adherent to both the cells and vessels. The contents of the vesicles or boils are transparent, sometimes being colourless, but more commonly yellowish; sometimes they consist of a thin pus, or they may exhibit a bloody or purulent discolouration. The fluid soon in thickness becoming thicker, opaque, and whitish or yellowish. The vesicle gives way; the fluid escapes, and is reabsorbed there, which soon falls off, leaving the skin smooth, or they may fall superficially necrotic. Erysipelas sometimes produces gangrene, but this is not a very lively rare occurrence. So long as this inflammation is confined to the skin, it does not produce suppuration; and the effusion of the cellular structure is so slight that termination in most cases is simple erysipelas. It may, however, become more severe in the part; and then we occasionally see the formation of abscess under the skin towards the centre or after the disappearance of the general erysipelas without. This inflammation generally marks a considerable surface of the skin, the inflamed part being irregularly circumscribed by a defined line. It spreads gradually to the neighbouring skin, declining and disappearing in the part first affected. Thus, we commonly see in various stages of erysipelas existing together in the same time in different parts of the skin. The part first affected is red and swollen; another part is elevated; while others exhibit induration and suppuration. Sometimes it leaves the part first affected, to appear at a distant situation. In origin, development, and complete termination within take place in one and the same spot. The neighbouring unaffected skin are frequently inflamed, and red streaks are sometimes seen leading to them.—(*See Lawrence, in Med. Clin. Trans.*, vol. 11.)

A time before the appearance of the return, and sometimes during several previous days, the patient experiences considerable indisposition, loss of appetite, his shiverings and violent pains in his limbs, accompanied sometimes with vomiting, and always with weakness and fever. Frequently these complaints occur, attended with a better state in the evening and first evacuation from the stomach. The tongue is moist, and covered with a yellow turgor. The pulse afterward has a dry, parched skin, constipation, an accelerated pulse, thirst, and other serious symptoms

of force. Blood drains from a vein which is a greater or less degree the inflammatory character. "Often, particularly when the head is the seat of erysipelas, the maxillary is principally affected, and erysipelas is of the kind called nervous, such as pain and oppression of the head, sometimes, some, or delirium. The tongue in such cases becomes dry and brown; but, according to Mr. Lawrence, this state of the organ is often owing principally to the contraction of the patient breathing merely through the mouth; the pulse is rapid and feeble, and there is great loss of sensibility strength; in short, the erysipelas is length and those called apoplectic. In other cases, the contraction and the nervous system are not much affected; but there is pain in the epigastrium region, and together with bad taste in the mouth, nausea, and vomiting; that is, ordinary indications of disordered stomach and intestinal canal, to which, as its cause, the local affection must be referred." (Med. Chr. Trans. vol. II, p. 8.) The last form of the complaint has been termed by French authors *erysipelas*.

The following is a description of phlegmonous erysipelas, as it sometimes appears when it attacks the head.

The attack is usually preceded by severe general complaints about the region of the head, and other symptoms very similar to those which indicate the approach of an inflammation fever. The heat is often accompanied with a little delirium, and almost always with depression of a more or less decided kind. The evening generally makes its appearance on the second night of third day of the fever, attacking the forehead, the cheeks, the nose, or eyelids. The swelling is slowly and smooth; but it is not distinctly circumscribed, and it gradually extends over each part of the face as described in the first article. The skin becomes of a bright red colour, and is usually having a tendency to a little heat, is often sometimes having a swelling of yellow. These colours disappear when pressure is made on the part affected, and very soon reappear when such pressure is discontinued. The patient experiences a burning heat and a disagreeable pricking in the part, rather than any acute pain; sometimes he complains of a very troublesome itching. The surface of the tongue is shining, red, and it is very, very irritable. But without tenderness, tension, or any sensation of throbbing. The effects are often so evident that the person cannot see, and the whole countenance is exceedingly disfigured. On more or less of the erysipelas, however, sometimes more about the forehead and face; they are filled with a transparent serum fluid, and thus a great resemblance to those which are attended by blisters. They commonly burst, or exude, on the fifth or sixth day, the fluid which is discharged sometimes extending the neighbouring parts. Frequently there is even a slight elevation at their base, which sometimes, in the worst sort of cases, assumes a purgative appearance, and falls rapidly into a state of complete suppuration. When the disease takes a more favourable course, the first heat becomes labile, the tension, dry, dry, and at the end of eight or twelve days the crabs, boils, and the scales formed in places which were occupied by the eruptions, fall off. The degree of danger depends mainly on the nature and other symptoms attending the affection of the face. When phlegmonous erysipelas attacks the face, the inflammation of the disease is dangerous, is very rare, (Lancet, vol. II, p. 117.) Mr. Lawrence represents phlegmonous as differing from simple erysipelas, in that the latter does not extend to the inflammation, which not only occupies the whole thickness of the skin, and extends to the cellular tissue, but even proceeds in the latter to suppuration and abscess. The skin and being often very much discoloured in the inflammation. Other writers, however, regard all examples of phlegmonous erysipelas cases which perhaps would be the consequence in the more view; and in fact, the exact line that should divide one form of erysipelas from another one, is always about being drawn. The affected part, which is at first firm, becomes softer, when diffused suppuration and tumor attend, with sloughs are under the skin. Experience proves that the seat of phlegmonous erysipelas is in the skin and cellular substance, and that the disease does not generally extend beyond the face. Mr. Lawrence differs from Mr. Hutchinson, in being always found the symptoms associated as

examined after death, and most no symptoms referable to any inflammation during life. "They may indeed become involved in the disease, when it is violent, and they may suffer partially when it extends to the intermuscular cellular texture, but they are not primarily affected in these cases, while in the majority of instances they do not suffer at all." (Lancet, Med. Chr. Trans. vol. II, p. 118.)

According to several writers, the seat of erysipelas is the greater number of cases is the very surface of the skin; its most violent and serious part—(Med. Chr. Trans. Med. L. 12, p. 225.) Perhaps it may be true, that the disease sometimes here, and is most intense; yet there can be no doubt that the affection generally extends more deeply, and affects the subcutaneous cellular membrane, particularly in cases of phlegmonous erysipelas. The remarks of Mr. Lawrence have taught him, as already noticed, that erysipelas is seldom confined to the skin, except in the slightest cases; often it takes place within cellular texture, extending a soft swelling; and this may be considerable, together with much tension and a burning surface, when a large part of the body or an entire limb is involved. (Med. Chr. Trans. vol. II, p. 118.) The affection of the cellular membrane, however, is very different from what happens in phlegmonous inflammation. In true erysipelas, healthy pus is rarely found enclosed in a circumscribed cavity; and when there is any secretion, in perfect manner, a foot is contained within the diseased part, almost like skin which a sponge would give. In such cases, the cellular substance is frequently torn.

It does not appear to me that any very exact information has yet been ascertained respecting the causes of erysipelas. We absolutely know nothing about the immediate cause; the prevailing theory concerning the predisposing causes are vague; and only those causes termed exciting appear entitled to much consideration.

Every surgeon is well aware, that possession of erysipelas is a disease of a low degree of a determined and peculiar nature, one feature of which is the inevitable production of this kind of inflammation upon the surface of the body.

With respect to the causes of erysipelas, it is the opinion of Mr. Lawrence that no difference prevails in this point between erysipelas and other inflammations. "The initial excitement of the vascular system is the long-continued disturbance of the stomach, alimentary canal, and liver, consequent on intemperance and excess, by the foundation of inflammation generally, and it depends on individual constitution, or on local causes, whether the skin or other parts shall be the seat of the disease. In most cases of erysipelas, the bowels and digestive system are more or less actively disordered, such disorder appearing sometimes to produce the cutaneous affection, sometimes to be excited sympathetically by it. Hence I should distinguish phlegmonous erysipelas, in which disease it may be observed, that the symptoms called bilious are commonly found also in phlegmonous cases." (Med. Chr. Trans. vol. II, p. 118.) Erysipelas may arise from external irritants of all kinds; from heat or cold; bites, scratches, ulcers, scabies, or other local causes applied to the skin; from wounds, abrasions, bruises, surgical operations, and all kinds of injury. The mechanical or chemical irritation of wounds, ulcers, or other local diseases will induce it. Neglect of previous preparations, moisture in diet, immoderate use of drinking, and other causes of the affected part, and in irregular degree of general action, are frequent causes of erysipelas after operations and wounds, and in the course of fevers and other local affections. When these several points are properly attended to, we shall not be much troubled with traumatic and local erysipelas. Irritating plasters, a heating food of dressings, and tight bandages, are common causes of erysipelas, whether in the case of wounds or operations. Light applications, and keeping the parts cool, are simple and efficient preventives. The most frequent causes, however, of this affection, after accidents or operations, is improper diet, that is, indigestion in simple food or fermented liquors. (Lancet, Med. Chr. Trans. vol. II, p. 118.) As far as I have seen, another very common source of erysipelas after wounds, is the taking of large quantities of wine.

According to Mr. Lawrence, simple erysipelas, and

the cases termed exanthematous, are mostly erysipelas, particularly from disorder of the portal vein or liver, and hence the epidemic fulvous and granular Erysipelatous erysipelas is most commonly produced by the wound of venesection, opening of the suppurative focus, as those of the paritis and obstetric, incised and lacerated wounds, and contused fractures; inflamed ulcers of the legs, and a fall due to persons who have large sores or ulcers rapidly healing; the wounds received in dissection, &c.

In most cases, erysipelas would seem to be primarily dependent on the state of the constitution. Thus, persons in the habit of drunkenness and other kinds of intemperance, and who in a state of intoxication meet with local excitation have erysipelas almost invariably in consequence of them. Other subjects, who lead more regular lives, experience, when they meet with similar causes, locally Erysipelatous inflammation.

The opinion of Hippocrates and Galen, with respect to the origin of this disorder from a corruption of the bile, is universally known to all informed in the profession of surgery. This old doctrine has been in some measure revived by Tissot and other writers in the last century, who attribute the cause of erysipelas to an acid humor, excessively alkaline one, diffused through the mass of the blood. But while I cannot dissent any evidence of the truth of this theory, observation obliges me to suppose, that the complaint seems frequently to be connected with disorder of the chylopoietic system, and especially of the liver.

A further proof that erysipelas is mostly dependent on constitutional causes, is, that the effusion is spontaneously frequent in autumn, or in any season, when the weather is succeeded by cold and wet.

Erysipelas attacks both sexes; but women are thought to be better, more subject to it than men, and the reason for this circumstance generally mentioned is, the greater delicacy and tenderness of the skin in females. But it would be quite as rational to expect those weaker and more amiable constitutions, and their secondary mode of life. In lying-in hospitals another character for the occurrence of erysipelas, near-born infants are often afflicted with a species of erysipelas, which begins in the umbilical region, and thence extends to the parietes. This case, which sometimes terminates in gangrene and places fatal, has been ascribed by some writers to injury done to the navel-string during labor, and by others to the bad air frequently allowed to accumulate in establishments of the above description, a cause which in other disorders, especially when it is first trivial, ultimately fails.

Sometimes the complaint is scarcely curable in one place when it makes its appearance in another, and when this tendency is evident in a great degree, the case is termed erysipelas scabularis, or erythrasma. La Moire has published a striking instance of this form of the disease. A child between nine and ten years of age was attacked with erysipelas of the scalp, forehead, and ears, which afterwards extended to the neck and then to the shoulders, "till his body and face became free from it; in proportion as the disease spread downwards, all the upper parts got well, so that in the end there were no signs of the infection of the body which had seemed, even down to the fingers and toes, the picture of all affections" (Med. Obs.).

A very uncommon variety of disease is a *generalized erysipelas*. No disorder is more subject than the present to relapses; but a remarkable case, sometimes attending the return of the complaint, is on hand sometimes strictly erysipelas. In different women, the erysipelated attack is occasionally such a story must not at the period when the disease should rise, cure. (Morgagni.) This particular nature of erysipelas has been observed in men: Larrey knew two men physicians, each of whom used to be attacked with erysipelas twice a year at the time of the epidemic; the other had only one attack annually, which was wont to happen in the beginning of the spring. My friend Mr. Mand, of Northampton, once labored with an erysipelas which was both venereal and venereal, affecting a body several times in the course of two years.

A difficulty has been started, that erysipelas is sometimes produced by contagion.—(Wells, in Trans. for the Improvement of Med. and Surg. Knowledge, vol. 2, art. 12, 1801. A. Knap, Sulla Gangrena Erysipelatosa, &c. Transac. p. 100, where Great Britain was Erysipelas

Contagiosa. See Thoms, 1825. Archib. in Med. Phys. Journ. vol. 17.) But, as Mr. Bateman has truly remarked, such cases are at all events extremely rare, and perhaps never happen in well-ventilated and cleanly houses.—(Sydenham, &c. p. 124.) As proofs of an epidemic description, the infection of many individuals in a single night is explained by the operation of the same exciting cause upon them all, without any suggestion of contagion. This part of the subject, however, is yet untraced. Mr. Lawrence believes that erysipelas of the face may be traced in some instances to contagion.—(See Med. Obs. Trans. vol. 36, p. 26.)

I think we must agree with Mr. Lawrence, that "a consideration of the signs, development and effects of erysipelas, whether local or general, leads us irresistibly to the conclusion that the nature of the infection is inflammatory. In its local leading characters it is redness, swelling, heat, and pain, and in its effects of effusion, suppuration, and sloughing, it agrees with what is called common or phlegmonous inflammation; while the general description proceeding and accompanying the local affection is often exactly alike in the two cases. Erysipelas, then, is nearly a suitable modification of cellulositis, or common and cellular inflammation. If we were to class these according to their general affections, we should place erysipelas between the exanthematous and phlegmonous. It is as difficult to class the former, not so circumscribed as the latter. The exanthematous are confined to the skin; erysipelas is some both skin and cellular structures; phlegmonous has its origin, even in the latter, the skin being so much involved.

The difference between erysipelas and phlegmonous, however, is not merely in the original and in degree of the disturbance: there is also a difference in kind. We may indeed say, generally, that phlegmonous is more violent and extensive than erysipelas, and sloughing of the cellular substance is more frequent in the latter than the former. The most striking and important distinction between the two affections is, that inflammation is confined to one spot in phlegmonous, and is strictly circumscribed in its seat, while it is diffused in erysipelas, and spreads without halt. This difference seems to depend on the different character of the inflammatory process in the former: the solidities called coagulable, coagulable, or seriginous lymph, which surround the inflamed part, forms a boundary between it and the sound tissue, which is opposite to the nature of erysipelas. In the latter, the effusion is serous; later, when matter is formed it is not confined to one spot, but becomes extensively diffused in the cellular tissue."—(Med. Obs. Trans. vol. 36, p. 17, &c.) These views correspond to those given by Mr. Hunter, whose original remarks on erysipelas are particularly valuable both in the pathological and the practical respects.

Like phlegmonous inflammation, erysipelas may be caused by any local irritation. Like other inflammations it may end in suppuration, though if a less perfect sort than that in which phlegmonous, the pus being rarely contained in a circumscribed cavity. The pulse, in phlegmonous erysipelas, is frequent, hard, sometimes full, and when the patients are thin, well blood has the same appearance, and is moved with the same kind of inflammatory action, as is taken away in other kinds of inflammations.

Mr. Lawrence says we agree with some medical authors, among whom may be placed Mr. Hunter, who regard erysipelas as a distinct species of inflammation, and capable of affecting various parts of the body as well as the skin. Some writers (the late) have referred to erysipelas certain inflammations of the conjunctiva, cornea, and lachrymæ; of the respiratory and alimentary trunks; of the various membranes in the head, chest, and viscera, and of the brain, spinal cord, and thoracic viscera. The distinguishing characters of erysipelas Mr. Lawrence refers to the possession of the exanthematous and cellular structures, in which it differs, and he therefore believes that such an affection cannot exist in parts so differently organized as solid membranes and the viscera. When the results of some of the viscera in question are carefully considered, it seems as if their structure were only that of erysipelas is connected with a particular state of nutrition, in which the inflammation, whensoever it is not would have a tendency to spread rapidly and extensively into the viscera, even thus and find its vent, positive further observations.

Treatment of Erysipelas.

Simple erysipelas, or extending a certain circumscribed area, yields to mild purgatives, and slight vegetable diet, with which moderate quantities of wine may be digested, and the saline mixture. Whether bleeding is right or not, in the treatment of erysipelas, is a point on which different sentiments prevail. The late, however, that venesection, in the earlier forms of the complaint, is now pretty generally allowed to be as unnecessary, as it is originally required in more severe eruptions. It is rather a prevalent notion, that it is unnecessary to remove blood in any case of erysipelas as frequently as in cases of other inflammatory diseases. We ought to be guided, however, in this respect, by the nature and extent of the inflammation, the state of the pulse, and other symptoms, never forgetting the patient's age, strength, and other important considerations. Another common belief is, that the patient will bear bleeding better in the evening, and in an open, pure air, than in a large city, and especially at an hospital. And it is remarked, that unless there be a considerable tendency to delirium or coma, blood-letting can seldom be repeated with advantage, at least in large towns.—(Pott's *Principles of Surgery*, 8th edition, *Symptoms*, p. 125, ed. 3.) Instead of this practice, the latter author recommends local bleeding and blistering, but not more or very near the diseased region, whereby he avoids protracting the inflammation, the frequency of which is better borne, after taking blood from erysipelasous parts, but Mr. R. Bell to procure a general condensation of the method, thought to observe, in relation to the above-mentioned form of bleeding patients freedom large, often, and it is an hypothesis which seems to be directing, greatly supported and justified, supposes having actually reported it as successful; and, as far as my observations extend, there is no business in waiting my opinion, that the abstract reasoning, whether a person living in town or country, should not likewise be the use of the blood, which might be rendered by otherwise important circumstances in the case. Alexander of Travers, and Parr, had a high opinion of the beneficial effects of plenty of fresh cool air in cases of erysipelas; but good air is generally beneficial in all diseases, and, perhaps, not more so in erysipelas than other disorders.

Mr. Lawrence supposes, that as erysipelas resembles other inflammations in its origin, symptoms, and effects, it should be treated on the same principles; that is, on the erysipelas plan. Venesection, local blood-letting, purging, and low diet are the first measures, to which saline and diaphoretic medicines may be afterwards added. He says, the latter three means are employed the latter vigorous treatment in the beginning seems to him most calculated to shorten the attack, and prevent the disease from spreading beyond its original seat. At the same time he states, that as the skin and cellular membrane are of secondary importance it is not so much necessary to arrest inflammation in them as in the vital organs; neither does the same reason for very active medicine exist as in affections of the eye, where a slight change of surface may seriously impair the utility of the optic medium; in our disorder and position; but the cellulars exhalation and nutrition, which erysipelas sometimes produces may render a hurt, in a great measure, irremediable, or may even destroy life. "The disposition of erysipelas is venereal; by resolution, therefore, reasons against meeting inflammation by active depletion. In many cases the disease passes through a certain course, and terminates favourably. It is sufficient to put the patient on low diet, to draw the alimentary canal, and then to use mild purgatives and diaphoretic. When it proceeds, as it often does, from an unhealthy condition of the alimentary canal, the removal of the internal disorder leads to the resolution of the local complaint. A cure, however, is observed, that resolution is sometimes effected both in curing the internal cause and in promoting the separation by resolution." Mr. Lawrence afterwards observes, that he does not mean to recommend that venesection equally serves, and in particular, that bleeding, whether general or local, are to be employed in all cases. In setting persons, in the robust, and those of full habit, in whom the pulse is full and strong, or where there is much heat and white tongue, in erysipelas of the head, attended with a moderate degree of affection of the sensorium, and especially in the very beginning of the affec-

tion, venesection will be proper; and it may be necessary to bleed largely, to repeat the venesection, or to follow venesection by some abstraction of blood. Under such circumstances, the other parts of the erysipelas plan must also be employed; that is, the alimentary canal should be cleared by an active purgative, which may be followed by saline and antiseptic, with the occasional use of mild opiates, and low diet should be insisted. As Mr. Lawrence adds, such can be made different from such a case, that that of an elderly person with a small and feeble pulse in the advanced stage of the disease. The interval between venesections is filled by numerous gradations, requiring corresponding modifications of treatment. The erysipelas plan itself embraces a wider range in part of degree, than blood-letting, local and general, with purging, salivation, the free use of salivary and antiseptic, and low diet, in the resolution of a mild erysipelas, with some saline medicine. Mr. Lawrence believes, that the treatment of erysipelas, like that of any other inflammation, should be modified according to the age, constitution, present health, and habits of the patient, and the period of the complaint. "In asserting generally that the erysipelas treatment is proper, I speak (said he) of the beginning of the disease, when the venereal and proper character of the affluence is apparent, and I am decidedly of opinion that, in some degree or degree, such treatment will always be beneficial in that stage. In many instances, active antiseptic measures are of the greatest service in lessening the severity both of the local and general symptoms. In others, the antiseptic use of alcohol with opium, and of diaphoretic with low diet, will be sufficient. When the affection passes in all well-distributed systems, the powers of life are soon seriously impaired, and all efforts must be directed rather towards supporting them, than combating the local affection, and have often been, with successful advantage under erysipelas of the face in its advanced stage, with repeated delirium, dry and brown tongue, prostration, short circumstances apparently desperate, by the free use of bark and wine." "The same writer does not local bleeding sufficient in the milder cases of erysipelas, and often necessary in the more severe ones, as an auxiliary measure. Purging, when practicable, he also deems as more efficacious than low diet, though objectionable on account of the painful state of the skin. Evacuation, he remarks, when applied to the external skin of some individuals, produces an effect analogous to erysipelas, but they exert no such influence over the internal skin, so much they may be applied freely and safely. In order to produce any decided benefit, he thinks that they should be applied in large quantities.

The authorities which may be cited in favour of the treatment of erysipelas by antiseptic principles, are Böhmer (1764), once Morison (1767), and A. C. 1801, 1802, 1803, 1804, 1805, 1806, 1807, 1808, 1809, 1810, 1811, 1812, 1813, 1814, 1815, 1816, 1817, 1818, 1819, 1820, 1821, 1822, 1823, 1824, 1825, 1826, 1827, 1828, 1829, 1830, 1831, 1832, 1833, 1834, 1835, 1836, 1837, 1838, 1839, 1840, 1841, 1842, 1843, 1844, 1845, 1846, 1847, 1848, 1849, 1850, 1851, 1852, 1853, 1854, 1855, 1856, 1857, 1858, 1859, 1860, 1861, 1862, 1863, 1864, 1865, 1866, 1867, 1868, 1869, 1870, 1871, 1872, 1873, 1874, 1875, 1876, 1877, 1878, 1879, 1880, 1881, 1882, 1883, 1884, 1885, 1886, 1887, 1888, 1889, 1890, 1891, 1892, 1893, 1894, 1895, 1896, 1897, 1898, 1899, 1900, 1901, 1902, 1903, 1904, 1905, 1906, 1907, 1908, 1909, 1910, 1911, 1912, 1913, 1914, 1915, 1916, 1917, 1918, 1919, 1920, 1921, 1922, 1923, 1924, 1925, 1926, 1927, 1928, 1929, 1930, 1931, 1932, 1933, 1934, 1935, 1936, 1937, 1938, 1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, 1948, 1949, 1950, 1951, 1952, 1953, 1954, 1955, 1956, 1957, 1958, 1959, 1960, 1961, 1962, 1963, 1964, 1965, 1966, 1967, 1968, 1969, 1970, 1971, 1972, 1973, 1974, 1975, 1976, 1977, 1978, 1979, 1980, 1981, 1982, 1983, 1984, 1985, 1986, 1987, 1988, 1989, 1990, 1991, 1992, 1993, 1994, 1995, 1996, 1997, 1998, 1999, 2000, 2001, 2002, 2003, 2004, 2005, 2006, 2007, 2008, 2009, 2010, 2011, 2012, 2013, 2014, 2015, 2016, 2017, 2018, 2019, 2020, 2021, 2022, 2023, 2024, 2025, 2026, 2027, 2028, 2029, 2030, 2031, 2032, 2033, 2034, 2035, 2036, 2037, 2038, 2039, 2040, 2041, 2042, 2043, 2044, 2045, 2046, 2047, 2048, 2049, 2050, 2051, 2052, 2053, 2054, 2055, 2056, 2057, 2058, 2059, 2060, 2061, 2062, 2063, 2064, 2065, 2066, 2067, 2068, 2069, 2070, 2071, 2072, 2073, 2074, 2075, 2076, 2077, 2078, 2079, 2080, 2081, 2082, 2083, 2084, 2085, 2086, 2087, 2088, 2089, 2090, 2091, 2092, 2093, 2094, 2095, 2096, 2097, 2098, 2099, 2100, 2101, 2102, 2103, 2104, 2105, 2106, 2107, 2108, 2109, 2110, 2111, 2112, 2113, 2114, 2115, 2116, 2117, 2118, 2119, 2120, 2121, 2122, 2123, 2124, 2125, 2126, 2127, 2128, 2129, 2130, 2131, 2132, 2133, 2134, 2135, 2136, 2137, 2138, 2139, 2140, 2141, 2142, 2143, 2144, 2145, 2146, 2147, 2148, 2149, 2150, 2151, 2152, 2153, 2154, 2155, 2156, 2157, 2158, 2159, 2160, 2161, 2162, 2163, 2164, 2165, 2166, 2167, 2168, 2169, 2170, 2171, 2172, 2173, 2174, 2175, 2176, 2177, 2178, 2179, 2180, 2181, 2182, 2183, 2184, 2185, 2186, 2187, 2188, 2189, 2190, 2191, 2192, 2193, 2194, 2195, 2196, 2197, 2198, 2199, 2200, 2201, 2202, 2203, 2204, 2205, 2206, 2207, 2208, 2209, 2210, 2211, 2212, 2213, 2214, 2215, 2216, 2217, 2218, 2219, 2220, 2221, 2222, 2223, 2224, 2225, 2226, 2227, 2228, 2229, 2230, 2231, 2232, 2233, 2234, 2235, 2236, 2237, 2238, 2239, 2240, 2241, 2242, 2243, 2244, 2245, 2246, 2247, 2248, 2249, 2250, 2251, 2252, 2253, 2254, 2255, 2256, 2257, 2258, 2259, 2260, 2261, 2262, 2263, 2264, 2265, 2266, 2267, 2268, 2269, 2270, 2271, 2272, 2273, 2274, 2275, 2276, 2277, 2278, 2279, 2280, 2281, 2282, 2283, 2284, 2285, 2286, 2287, 2288, 2289, 2290, 2291, 2292, 2293, 2294, 2295, 2296, 2297, 2298, 2299, 2300, 2301, 2302, 2303, 2304, 2305, 2306, 2307, 2308, 2309, 2310, 2311, 2312, 2313, 2314, 2315, 2316, 2317, 2318, 2319, 2320, 2321, 2322, 2323, 2324, 2325, 2326, 2327, 2328, 2329, 2330, 2331, 2332, 2333, 2334, 2335, 2336, 2337, 2338, 2339, 2340, 2341, 2342, 2343, 2344, 2345, 2346, 2347, 2348, 2349, 2350, 2351, 2352, 2353, 2354, 2355, 2356, 2357, 2358, 2359, 2360, 2361, 3451, 3452, 3453, 3454, 3455, 3456, 3457, 3458, 3459, 3460, 3461, 3462, 3463, 3464, 3465, 3466, 3467, 3468, 3469, 3470, 3471, 3472, 3473, 3474, 3475, 3476, 3477, 3478, 3479, 3480, 3481, 3482, 3483, 3484, 3485, 3486, 3487, 3488, 3489, 3490, 3491, 3492, 3493, 3494, 3495, 3496, 3497, 3498, 3499, 3500, 3501, 3502, 3503, 3504, 3505, 3506, 3507, 3508, 3509, 3510, 3511, 3512, 3513, 3514, 3515, 3516, 3517, 3518, 3519, 3520, 3521, 3522, 3523, 3524, 3525, 3526, 3527, 3528, 3529, 3530, 3531, 3532, 3533, 3534, 3535, 3536, 3537, 3538, 3539, 3540, 3541, 3542, 3543, 3544, 3545, 3546, 3547, 3548, 3549, 3550, 3551, 3552, 3553, 3554,

larger of manifestation is needed, sometimes often occur, which spread through the system and under the integuments is a surprising effect. "From the inside to the outside and over the glister manifest." In the first case which came under the eye of Mr. Hutchinson, this gentleman's plan of treatment, in addition to the usual medical means, consisted of first binding by means of suppurative issues, followed by incisions. Subsequently, however, he has adopted the method of making several free punctures with a scalpel on the inflamed surface in a longitudinal direction through the integuments, and then to the removal of the matter as far as possible, and before any suppuration has taken place. These incisions may be about an inch and a half in length, and in three or four places, and every six hours from the morning till evening, at the interval of twelve, which the disease is found to progress. Mr. Hutchinson states, that these incisions will yield between fifteen and twenty ounces of blood, and give relief to the patient, in the same time that they form channels for the escape of blood, and the presence of heat or matter. After the operation, dressings or external lotions are required.

By the pusillous kind of treatment, Mr. Hutchinson thinks the fatal termination of the disease may be rendered less frequent, and sometimes entirely wholly avoided. He supports this assertion by observing, that he has treated a case in the Royal Hospital for the last five years, during which the pusillous was followed.—(See *Med. Clin. Trans.*, vol. 2, p. 253, &c.)

Mr. Lawrence thinks the most powerful means of arresting the complaint is by making one or more long incisions through the inflamed skin with the subcutaneous and cellular texture, which are the seat of the disease. These incisions, he asserts, are followed very quickly and almost instantaneously by relief and cessation of the pain and tension; and the alleviation of the local suffering, he assumes to be accompanied by a corresponding interruption of the inflammation, whether it be in the stage of effusion, or in the more advanced period of suppuration and disorganization. Mr. Lawrence further asserts that this treatment is employed to the greatest advantage at the beginning, since it prevents the farther extension of inflammation and the commencement of suppuration and disorganization. At a more advanced stage the incisions bear the extent of suppuration and gangrene; and at a still later time they afford the readiest means for water and drainage, and facilitate the commencement and progress of suppuration and disorganization.—(*Med. Clin. Trans.*, vol. 11, p. 67, &c.) The great points in which a diversity of opinion exists respecting the treatment by incisions are the period when they are really necessary, and those manner and extent. Believing from various observations that phlegmonous erysipelas, when properly treated, does not tend to terminate in extensive gangrenous necrosis, and suppurative under the skin as Mr. Lawrence's account would make it appear, but, on the contrary, then it frequently abates of resolution, and often commences suppuration which may be safely opened at such a point as desired, I cannot acknowledge the wisdom or utility of making incisions for the prevention of crisis, the occurrence of which in all is quite a matter of uncertainty. Thus, though Mr. Lawrence has advised from several of the above, in relation to punctured early and free incisions, and these had the effect of preventing extensive suppuration and disorganization, the conclusion is certainly without satisfactory proof; and a case might have taken place with well without more. To the practice, therefore, in the early stage of the disease I should object as unnecessary. At a more advanced period, however, when matter is formed, I am decidedly an advocate for making a free opening for its discharge, but not for relieving pain, or making different wounds for the sake of any other purpose, nor for using the scalpel with equal caution to the use of the lancet, and sometimes of its edge to make with it a path requiring a foot or yard more for its introduction. Whoever looks into the reports of the treatment, as detailed in the *Lancet* and other works, cannot fail to be struck with the following facts. Several patients, treated in this way, have not been saved, and some have certainly gone out of the world in a very short time. Whether this arises from the shock of an excessive wound on the constitution, it is very difficult to state, or from profuse suppuration, or other causes, it is needless to enquire. In one or two instances, the cutaneous nerves are well

as large, and the arteries, more or less spared, and a partial paralysis ensued. Against the proposed treatment by numerous or long incisions I must therefore constantly protest: in the early stage the practice of incisions in any way is not only indicated for the reason above explained; and at a more advanced period if suppuration or gangrene commences, a prompt and free opening is undoubtedly required according to all the established principles of surgery, but not a number of pyramidal incisions. Dr. Wilson, of Greenock Hospital, makes use of kinds of erysipelas sometimes small pustules in the part, and repeats them in the morning and evening repeated twice a day; and often in high cases three or four times in the twenty-four hours. The quantity of fluid (as it is not blood alone, but blood and effused serum) which these punctures discharge, amounts sometimes considerably, he says, need never excite any alarm. With this practice he joins the application of the styptic solution, liquor potassæ, cast. and tincture of rhubarb. He also employs a lotion composed of hyssop, cast. and camphorated spirit, and water—(See *Med. Clin. Trans.*, vol. 11, p. 263). Of this method I still more observe that it has no effect to any let ever to cure a trial; but that, if I were the patient, I should rather select it, than to the bold sweeping incisions or numerous deep cuts which have been recommended by physicians whose opinions on other points in surgery I sincerely respect.

In this country, during the winter months, and especially in variable seasons, phlegmonous erysipelas as it is here called, is the most dangerous of local affections, as before, wounds, &c., and by speedy running and suppuration, this disease has often proved fatal, although the original disease was circumscribed and inconsiderable.

I have frequently known this kind of erysipelas to originate from a slight wound on the hand, and in a few days involve the whole arm in the suppurative process. And although the matter is torn severely penetrated the tissue, yet the matter would diffuse itself beneath the limit of the last, and require the most professional efficient remedies to prevent death by the pain and irritation occasioned by dissection.

Mr. Lawrence's plan of treatment has been intended with equal success under my own observation, the threatening symptoms subsiding immediately after long and free incisions were made through the skin and subjacent adipose and cellular texture. Professor Beinhart of this city has had opportunities of testing this practice to considerable extent, and he informs me that he has uniformly obtained the most satisfactory results.—(See.)

What is termed subcutaneous erysipelas is generally considered to be an acute case for incision and free evacuation, and almost always to require a liberal plan of treatment. In short, the field practice, in every case of erysipelas, is to let the resolution be regulated in a given measure by the state of the constitution, the stage, the strong or relaxed condition of the system, the sort of fever accompanying the disorder, the age, occupation of the patient, and the particular stage of the complaint. At first, though antiphlogistic treatment may be the only safe plan, circumstances afterward change so considerably that this must be abandoned, and a method quite the reverse of it vigorously adopted.

With regard to the treatment of gangrenous erysipelas, nothing more need be said than what is contained in the article on *Phlegmon*.
